*Wakley's* energy and fearlessness, together with his fine physique, must have made him an engaging personality, and this impression is confirmed by the charming sketch by Sir Eldon Lanes; a reproduction of it in colours forms part of the centenary supplement, an advance copy of which we have by the courtesy of the Editor been permitted to see.

A small group of brilliant assistants, some of whom, such as Wardrop and Lawrence, attained afterwards to professional fame. Many enemies were made in the fight for the reform of the Corporations and of the great hospitals and schools, but in time they were won over. A striking proof of the reconciliation which had taken place between *Wakley* and those whom he had most bitterly assailed was afforded in 1849, when a malicious action was brought against his son, Mr. T. H. *Wakley*, at that time a young surgeon on the staff of the Royal Free Hospital. All the surgeons who came forward to give evidence in favour of the defendant had been most severely handled in the early volumes of the *Lancet*, and among them was Mr. Bransby Cooper, who had suffered under a most cruel and not quite fair attack one-and-twenty years earlier.

The actions at law which poured in upon the plain speaking and undaunted editor, if not decided in his favour, were treated as moral victories, and the general feeling was that the *Lancet* had done its duty.

It is not surprising that the *Lancet* should have been so successful in its early days, and that it should have been so successful in its later years, and that it should have been so successful in its present day.

In the absence of a serious complication, such as haemorrhage, a lingering first stage never does any harm, and there is always time to remedy any displacement or to decide upon some method of treatment, if necessary, which will probably be less dangerous than that of the forceps operation. A lingering second stage, as long as the "pains" are not failing or becoming continuous, is less harmful than a rapid delivery with the forceps. Patience first. It is true that delay in the birth of the child always causes anxiety in the patient or her relatives, and even perhaps suspicion, whereas a quick delivery is apt to bring credit to the practitioner—not by any means always where it is due. The proper time to use the forceps, when the delay is due to inefficient pains, is when they are becoming inefficient, not when they have become so; if pains have ceased, post-partum haemorrhage is lurking round the corner.

And lastly, with reference to the use and abuse of the forceps when the delay is due to disproportion. In no instance is an accurate diagnosis of more importance. The practitioner must not be unduly influenced by the external measurements of the pelvis, which indicate mostly the shape of the pelvis, neither should he regard the pelvis as normal if his finger will not reach the promontory of the sacrum. A knowledge of the length of the true conjugate is only of material use when it is so small that obviously a child could not pass the brim of the pelvis without mutilation, if at all, or when it is so large that there would be no difficulty in spontaneous delivery. The majority of cases of disproportion do not come into either of these categories, and it is in this class of case, in which the conjugate is between  $3\frac{1}{2}$  and 4 inches, that so much harm is done when using the obstetric forceps.

In this medium class of contraction the practitioner should not interfere unless he is forced to, and if, as I have suggested, he will always regard extraction with the forceps as an "emergency operation" he will be far less tempted. He should be guided by the condition of the mother and child, and if this remains satisfactory he should hold his hand. It is far better that the second stage of labour should last six hours than that the mother and child should be injured or killed.

Especially should what is known as the high forceps operation be avoided, for it is an extremely dangerous one and often most difficult. Munro Kerr has reported that since its abolition in the institutions with which he is connected, spontaneous delivery has become much more common. Such an operation should never be an operation of choice.

The higher the head is in the pelvis the longer should the operator wait before applying the forceps; inefficient pains are an extremely rare cause of the head being arrested high up. In many cases of delay due to disproportion labour terminates spontaneously and safely after a second stage of six or even more hours, though it would have ended disastrously had the forceps been used. Statistics show that 80 per cent. of border-line cases of disproportion will, if left to Nature, end in spontaneous labour. After all, the practitioner can always fall back on the forceps if Nature fails.

The use of the forceps in cases of medium disproportion is responsible, as Eardley Holland has shown, for a very large number of stillbirths, and this, especially now that the number of children born is very little higher than the number of people dying, is alarming.

To say that unfortunately the baby has died because its head was too large or the mother's pelvis was too small in most cases reflects more on the acumen of the practitioner than on the anatomy of the patient. The obstetric forceps should be used to deliver a live child; the delivery of a dead child does not warrant a testimonial for using it.

If the head of the child is movable above the brim of the pelvis the forceps should never be employed. If the head is fixed in the brim and does not, after a fair trial, undergo enough moulding to come through, the use of the forceps is really an abuse. If the head is moulding sufficiently to come through the brim, however slowly, leave it to Nature. To assist in such cases with the forceps will in most cases mean serious injury or death to the child, and not infrequently injury to the mother. If there is the

least doubt about the head being able to pass the brim, do not use the forceps, as this only increases the danger if Caesarean section is decided upon.

A generally contracted or funnel-shaped pelvis is commoner than is usually supposed. In any case, therefore, in which the head has difficulty in entering the birth canal, the measurements of the outlet should be taken, and a very careful examination should be made of the nature and the presentation.

It has been said with some semblance of truth that gynaecologists would starve if it were not for birth and midwifery. The forceps is an extremely valuable instrument when used with intelligence and in suitable cases so is poison gas.

## II.—JOHN FAIRBAIRN, M.B., F.R.C.P., F.R.C.S., Obstetric Surgeon, St. Thomas's Hospital.

I do not wish to add further counts to the serious indications of the obstetric forceps in the opening paper or discuss indications or contraindications, but rather to try to put the forceps in its proper place in our defensive system against undue prolongation of labour. My purpose will be to show that unless instrumental delivery is clearly and universally recognized as our second and not our first line of defence, our plan of campaign is conceived on wrong lines. It is accepted as a general principle throughout the practice of medicine that the prevention of abnormal functioning must always be our first endeavour, and the application of this principle to midwifery practice means that the chief responsibility of the medical attendant is the elimination of the factors interfering with normal parturition—in other words, the first line of defence.

The obvious retort to this proposition is that it is purely academic—the first line of defence cannot hold because little is known and still less can be done to eliminate the inhibiting influences on labour, and therefore you will all continue to fall back on the forceps. The more of you that make that reply, the more will my position be strengthened. My point is that hitherto reliance has been placed almost entirely on the forceps, thus acting as a drag on progress towards our primary objective; until we try and discover what can be done, we will go on as we have in the past, but once we concentrate on holding the first line and making a stand there, then, in the event of failure, it is right to fall back on our second line.

In illustration of what has already been done by the application of a similar academic principle and of reformation along physiological lines, I will quote the analogous case of infant feeding. Formerly our attention was largely directed towards perfecting substitutes for the natural food of the baby, and great success was attained in adapting the milk of another mammal, so as to enable the human infant to thrive on food never intended for it. Our textbooks devoted no more than a line or two to breast-feeding. There was a pious statement that it was best for infant and mother; there was a list of its contraindications with instructions as to how to disperse the milk when suckling was not carried out, and that was about all; whereas the preparation of substitutes and the modification of cow's milk and other possibilities took up pages and sometimes a whole chapter. No attention was given to the causes of failure to suckle and how they might be removed, or to the means of increasing mammary activity when inefficient or to the investigation of the reasons why the baby did not thrive satisfactorily at the breast. Now much of the work of the School of Mothercraft, which I instance because I happen to know it, is the re-establishment of breast-feeding after needless weaning of the baby. At any time may be seen there living evidence of what ten years ago would have been thought impossible, in the shape of mothers who have previously failed and failed repeatedly, and mothers whose infants have been weaned for six weeks or more, successfully nursing a contented baby. The error was that our energies had been devoted to providing a substitute for the function we did not attempt to control. We were clearly on wrong lines, for, however successful, such substitutes could never be as good as the real thing. We should rather have studied the function of lactation and how to improve it when defective—precisely what we are now learning to do.

given to commentators. Inadequate remuneration for work done under pressure of circumstances is very apt to spell haste, while haste in midwifery generally means middlebrow and unnecessary interference, with

all its disastrous train of sequels.

Mr. Berkeley opened his paper by drawing atten-

tion to the lack of efficient teaching on such practical

points as the proper method of application of obstetric

forceps, and pointed out that in the last resort the

responsibility for this inefficient teaching rested upon

the General Medical Council, and still more upon

the various examining bodies, which did not insist

upon certificates of really adequate practical teaching.

It would be laughable were it not so tragic to consider

the elaborate care which is taken to teach students

the technique of surgical operations which most of

them will never have occasion to perform, while the

technique of such obstetric operations as the applica-

tion of forceps, which any one of them may quite

possibly be called upon to perform within twenty-four

hours of going into practice, is left to be picked up at

or junior assistant. Many practitioners must have

had the experience of having to face an abnormal

maternity case very early in their professional careers,

and must have vivid recollections of the sense of

frustration and unpreparedness which then possessed

them. If it be true—and all the indications point to

its being so—that the main difficulty in the teaching

of obstetrics is that of obtaining sufficient clinical

material, then that is another very strong argument

for the increase in the number of maternity hospitals

throughout the country.

Mr. Berkeley next discussed the more common

mistakes in connexion with the actual technique of the

operation. These have been dealt with again and

again, and must continue to be reiterated until, as

a result of better and more practical teaching, both

of the public and of the profession, conditions improve

and correct technique becomes instinctive. He

pointed out the value of exact knowledge of the

mechanism of labour, and explained how the appli-

cation of forceps could very easily interfere with this

normal mechanism unless proper skill and care are

exercised. In regard to the actual indications for the

use of forceps he emphasized the opinion that they

should be used to anticipate danger to the mother or

child, and not when one or other is already in danger.

Before using the obstetric forceps the relative sizes

of the pelvis and the head, the condition of the genital

canal, the strength of the uterine contractions, and

the state of the child should all be ascertained. If

this were actually done and the treatment based upon

the results of such an examination, the application of

forceps would undoubtedly be much less frequent than

it is. The legitimate and proper use of obstetric

forceps is one of the most beneficial operations known;

their indiscriminate use is to be deprecated from every

point of view.

Mr. Comyns Berkeley then went on to discuss

indicated labour, which is perhaps the most common

operation alleged for the operation, and pointed out,

what is so often forgotten, that in the absence of such

complications as haemorrhage a lingering first stage

never does any harm either to the mother or to the

child; even a lingering second stage, so long as the

pains are not falling or becoming continuous, is less

harmful than a rapid delivery with forceps. It may be

taken as an axiom that delay in labour is, *per se*,

seldom a cause of danger. The relatives and friends

of the patient, however, think otherwise, and many a

man has been hurried into the premature application

of forceps or the adoption of some other method of

rapid delivery against his own better judgment

simply because he had not the courage and confidence

to withstand the moral pressure of the anxious rela-

tives. It is another great advantage of hospitals and

nursing homes that they leave the judgment of the

medical attendant untrammelled by distracting con-

siderations of a more or less domestic or personal

nature. In connexion with moderate degrees of con-

traction of the pelvis, Mr. Berkeley referred to Munro

Kerr's statistics, which, amongst others, have shown

so clearly the enormous value of leaving the labour to

Nature. Eighty per cent. of borderline cases of dis-

proportion and spontaneously when left to Nature.

This is a statement which cannot be over-emphasized.

The value of head moulding is not sufficiently appre-

ciated. In how many cases, when a practitioner

knows that he has to deal with a case of slight con-

traction of the pelvis, and thinks that in all probability

forceps will ultimately have to be applied, does he

proceed to apply forceps forthwith, in order "to get

the case over," instead of giving the patient as long

as possible to obtain the full benefits of moulding?

No treatment could be more mistaken. Cases of diffi-

culty not too great to be overcome by Nature should

be left longer in the second stage, provided the general

condition of both patients is satisfactory, than cases in

which there is no special element of difficulty.

Dr. Fairbairn's contribution to the discussion was

characteristically thought-stimulating. He laid em-

phasis mainly upon the importance of ante-natal care

so that the condition of the patient and the circum-

stances of the confinement generally should be as

far as possible. His paper is full of suggestive

hints which will well repay perusal.

Of the details of the discussion itself it is not our

intention to write. But we believe that there is no

specialist in obstetrics who would not support Mr.

Comyns Berkeley's main contentions whole-heartedly.

As a protagonist in a debate Mr. Berkeley naturally

stated his case as emphatically as the facts of his

experience warranted. It should be remembered that

the experience of a hospital obstetrician, and more

particularly of a hospital gynaecologist, gives him a

very different outlook from that of the practitioner,

who sees mostly just his own or his immediate neigh-

bour's work. The specialist is able to have a very

much wider outlook, but at the same time he of

the incontrovertible fact remains that nearly half the

work of a gynaecological ward is due to bad midwifery,

and it is probably true to say that more of the bad

midwifery lies in the abuse of forceps than in any

other single procedure. If all the obstetric forces in

the world were cast into the depths of the sea there

would be less reparative gynaecology than there is

now; but there would be a still more remarkable and

praiseworthy reduction in the need for reparative

operations if the forceps were retained in the obstetric

armamentarium, but always used properly and only in

accordance with suitable indications.

The keys to the solution of the problem are, first,

ante-natal care. "Forewarned is forearmed," and

nine labours are made difficult by lack of adequate

foreknowledge for every one that is inherently and

persistently difficult. This preventive aspect of

obstetrics, which is the most satisfactory development

of midwifery in our generation, was ably discussed in

the second paper by Dr. Fairbairn. In the next place,

the patient, however, think otherwise, and many a

man has been hurried into the premature application

of forceps or the adoption of some other method of

rapid delivery against his own better judgment

simply because he had not the courage and confidence

to withstand the moral pressure of the anxious rela-

students and post-graduates. That the application of forceps should be regarded as in every way a surgical operation was no doubt absolutely true, but the practicability of the matter was different. Better-class or hospital practice and poorer-class practice were so different that they could not be considered together. No measure of asepsis could possibly be attained by anyone working alone—antisepsis was alone practicable and should be their mainstay. He was afraid that too often consultants were apt to forget the conditions under which the general practitioner often had to carry on his work. Shaving the vulva was obviously the proper procedure; but did the advocates of this measure realize how often the patient refused point blank to permit it and declined to have anything more to do with the doctor who suggested it? He was certain that prolapse readily occurred after a perfectly spontaneous labour without laceration. He thought that the minimum lying-in period should be extended to fourteen days. Dr. Ford was a warm advocate of Dr. Ballantyne's method of correcting malpositions by means of a pad and binder. He thought that the fear of performing Caesarean section in probably infected cases was allowed to exceed its proper bounds.

Mr. Louis Rivett (London) thought that the abuse of forceps was entirely due to failure of ante-natal care. He did not think that the use of forceps was a factor in producing prolapse if application was made after the head had entered the cervix. Damage to the perineum was a very small factor in causing prolapse; prolapse was very rare after complete rupture. He was strongly opposed to attempts being made to stretch the cervix digitally; it practically always meant tearing, not stretching. He regarded the application of forceps to the head before it was engaged in the pelvis as an absolute abuse of forceps. He would like to ask Mr. Berkeley how many times he had seen a student deliver a patient, and if he had ever shown even his house-surgeon how to apply forceps. He agreed that it was very difficult to persuade patients to have the vulva shaved.

Dr. D. McASKIE (Southsea) said that to general practitioners the remarks of Mr. Comyns Berkeley were disturbing. They had often gone home in the early hours of the morning feeling happy that they had saved two lives. Now they should go home regretting they did not see the woman a month earlier and correct the malposition or malpresentation. Seventy per cent. of the midwifery cases were now in the hands of the midwives. Midwives did not palpate the abdomen; but if this method of examination was insisted upon the midwife could diagnose an occipito-posterior case and call in the doctor in time. He was now often called in only when Nature had failed, and had to make the best of a bad job. It was too late to convert an occipito-posterior to an occipito-anterior; too late to convert a mento-posterior into a mento-anterior; too late to turn a brow case or change it to a face or vertex presentation. This condition of things was very annoying and should make Mr. Comyns Berkeley pity the lot of the general practitioner. They had still got these cases to deal with, and Mr. Comyns Berkeley's general principles did not help them much in dealing with them. Mr. Comyns Berkeley did not give the indications for the use of forceps, but referred them to the textbooks. These seldom devoted a full chapter to the subject, but dismissed it in a few lines, saying they had been mentioned under the various forms of labour; and when they looked them up they found that the authors differed in their treatments. It was disappointing, therefore, that when this subject was brought up for discussion a full discussion of the subject was not entertained. In ante-natal treatment occipito-posterior cases were changed to occipito-anterior cases and breech cases to vertex cases. In occipito-posterior presentations nine out of ten cases rotated to the front, and Dr. McAskie questioned the advisability of interfering with them. He thought that those cases in which flexion occurred should be left to Nature; and only those that showed extension of the head should be changed to occipito-anterior cases. Mr. Comyns Berkeley said that the mechanism of labour was a natural process; but he did not tell them that Nature sometimes failed. There was failure of flexion and internal rotation sometimes in occipito-posterior positions. There was failure of exten-

sion in face cases, and in face cases they had to pull the chin down when it came through the pubic arch to prevent Nature presenting the mento-vertical diameter at the outlet. Failure of flexion and internal rotation in normal labour was not made much of in the English textbooks; but on the Continent failure of flexion and internal rotation in normal labour was put down as an indication for the use of forceps. As regards axis-traction forceps, in nineteen out of twenty cases in which they were used the head was in the pelvic cavity and ordinary forceps were just as good. Even in persistent occipito-posterior cases where the head was high experience had taught him that they were often better than axis-traction forceps. He had had a case of persistent occipito-posterior position in which his axis-traction forceps slipped three times. He sent for a neighbouring practitioner to help him; his colleague did not possess axis-traction forceps, and he put on ordinary forceps, and they did not slip. He was called again to assist another colleague whose axis-traction forceps kept slipping; he put on his forceps without the axis-traction and they did not slip. Mr. Comyns Berkeley said that forceps cases were more liable to become septic. This was not the experience of the general practitioner. He feared more the cases in which something was left behind in the uterus, and this was often due to delay in the use of the forceps, resulting in an atonic uterus. Mr. Comyns Berkeley had said that the morbidity in forceps cases was greater than in normal labour. That was comparing abnormal cases with normal cases, and was not fair reasoning.

Lieut.-Colonel ANDREW BUCHANAN, I.M.S., demonstrated by means of models how the anterior part of the head could be made to come down. He said that the teaching of midwifery contained too many distractions so that the student was unable to grasp the ordinary mechanism of labour. He claimed that his models simplified the understanding of the elementary mechanical principles of parturition.

Dr. JOHN CAMPBELL (Belfast) said that Mr. Comyns Berkeley had given such sound and sensible advice that no fair adverse criticism was possible. Examination of the woman during pregnancy was most important; by it they could recognize whether there was pelvic contraction, of such a degree as to prevent the head from coming down naturally. They had available not only the usual methods of abdominal and vaginal examination, but also the measurement of the pelvis by x rays. By comparing the radiogram of the patient with that of a normal pelvis they could get a very accurate idea of the size of the pelvic canal. The use of every method of examination before labour would get rid of the "bad forceps" cases and the "failed forceps" cases. Caesarean section was now so safe and satisfactory for both mother and child that it should more and more take the place of severe attempts at forceps delivery. One of the most frequent mistakes made was to attempt to deliver before the cervix was fully dilated. Too often the forceps was applied as soon as the cervical canal was wide enough to allow of the introduction of the blades. Fortunately they had a remedy in the judicious use of morphine. By it they could gain time; they also soothed the patient and mitigated the anxiety of the relatives and friends until the cervix had become fully dilated. Provided the case was one in which the use of forceps was legitimate, the danger of a forceps operation was very greatly lessened by the simple rule that the cervix should be fully dilated before the forceps was resorted to.

Mr. R. J. JOHNSTONE (Belfast) thought the discussion should be a great lesson to the teachers of midwifery present, as from the dreadful list of disasters recited by the opener it was evident that students were not properly taught before being turned out on the world. In his opinion, if the os were fully dilated in a normal case there could be very little danger in applying forceps to shorten the second stage, and when a woman had been in labour for hours he could see no objection to putting a period to her pain. In his experience sepsis was less frequent after forceps than after unassisted deliveries. He thought that rupture of the perineum, and especially subcutaneous rupture of the levator ani, was rather prevented than produced by full chloroform anaesthesia and forceps delivery.

the Rev. H. Kirkland-Whitaker, M.A., M.D., Chaplain of the women's ward, Dr. Isabel Pulteny, 2, Brynston House, Bantled Downs, Sutton, Surrey, or to the secretary Place, London, W.1.

# AN ISLAND WITHOUT DENTAL CARIES.

Dr. Michael Granmar of Madeira read a short paper in the Physiological Section of the meeting of the British Association in Liverpool on some recent researches he has been making among the people of Porto Santo, the northern island of the Madeira archipelago. He gave a detailed account both of the geology of the district and of his own mineral discoveries, and also a review of the meteorological and sea-current conditions which govern the climate. The local springs are highly mineralized with chlorides, carbonates, and sulphates, in contrast with the sweet waters of Madeira. A thorough geological survey is long overdue and would yield important results. Treachery is the main feature of the Porto Santo volcanic object, as compared with the basaltic of Madeira. Christopher Columbus resided at Porto Santo, was married there, and the house in which, according to tradition, he lived is still shown. Dr. Granmar suggested that the seeds and other jetsam thrown on the shores of the island by the sea currents helped to convince the great navigator of the existence of lands beyond the setting sun. The climate of Porto Santo is fresh and sunny, and less humid than that of the main island of the group, as is evidenced by the contrast between the vegetation at Porto Santo and the weedy profusion of escultans at Madeira. The features of the diet of the people at Porto Santo are that they take no milk or green vegetables and nothing involving grinding mastication. They take their food cold, and their main sustenance is derived from maize boiled with a modicum of lard, with a slight addition of fish and an onion or two. Dr. Granmar saw no case of scurvy, but many instances of pulmonary disorder. The absence of diarrhoea and alimentary ailments was remarkable, and the mineralized waters seemed inimical to intestinal parasites. Dr. Granmar found no existing instance of malignant disease. Traditionally some cases have occurred, but no form of cancer has taken root at Porto Santo, and Dr. Granmar is inclined to associate this exemption with the simple feeding of the people and with the absence of animal fats, except the small quantity of lard consumed with the maize. In this connexion, too, he lays stress on the marked absence of alimentary disorders premortality of cancer liability. Nearly 3,000 people live at Porto Santo, and the main object of Dr. Granmar's visit was to inquire into the boasted immunity of the inhabitants from dental caries. Six hundred natives were examined, and yielded 23 cases of well established caries. All of these people except seven had come from Madeira, and only two of the seven showed the sign which characterizes the Porto Santo dentition. This sign consists of a slight yellow band which develops in early life on the upper incisors. It occurs with a regularity which, in Dr. Granmar's opinion, clearly indicates a vitalizing permeation of the blood fluids among the columnar structure of the enamel, associated with the stain and protective influence against the access of caries. Both the columnar structure of the enamel, associated with the stain and protective influence against the access of caries, which is growing in reputation and application in the colonies of Portugal, but Dr. Granmar wishes to be regarded as a pioneer whose work and inferences should be confirmed before any steps are taken to make the district available as a spa in a winterless region. Dr. Granmar showed a skull of a Porto Santo man of about 60 years of age taken promiscuously from an exposed grave, the teeth in this skull (which is now deposited in the museum of the Royal

insulin. Thereafter it is recommended that the patient should be returned to his home and placed under the supervision of his medical attendant as regards his diet and general treatment. Examination of the urine ought to be carried out daily to determine the presence of sugar, and if sugar be present, a daily quantitative examination should be done. In cases progressing favourably a blood sugar estimation is needed at least once a month. It is emphasized that unless these preliminaries are carried out in the case of each patient the satisfactory treatment of diabetes with insulin is almost impossible, and is certainly attended with very great danger. Not all diabetics require insulin, and in some cases—for example, renal glycosuria—serious harm may follow its administration. The Ontario Board of Health disclaims all responsibility for accidents which may follow the administration of insulin; this matter is entirely in the hands of the medical practitioner himself, and he must take the responsibility for the individuals who receive the treatment and also for the amount of insulin given. The pamphlet goes on to describe the standardization of insulin, the method of administration (subcutaneous, not intramuscularly, nor too near the skin surface, usually about a quarter to half an hour before food), diabetic treatment in diabetes, the treatment of acidosis and of coma, the complications of diabetes, and the dangers in insulin treatment. In conclusion, a memorandum is set out for diabetics using insulin. Accurate adjustment of diet and insulin dosage, it is insisted, are essential for successful treatment. Excessive exercises or heavy work should be avoided. Hypoglycæmia is serious; the patient should remember the symptoms and cure, and always have carbohydrate in some form readily available. If the supply of insulin be exhausted the patient should decrease the diet by one-third, and rest; the former diet should be resumed when fresh insulin arrives. Enough insulin for one month should be ordered, as it will not deteriorate in that period.

## THE GUILD OF ST. LUKE.

The annual service of the Guild of St. Luke, the Evangelist and Physician, held at St. Paul's Cathedral on St. Luke's Day, Thursday, October 18th, at 7 p.m. Seats will be reserved for medical practitioners and students, all of whom are invited to attend whether they are members of the guild or not. This reopening of the medical schools, affords a timely opportunity for men and women engaged in medical work, as well as for all for whose health they strive, to join together in public worship. The Guild of St. Luke, which was founded in 1864, has for its object the mutual encouragement and support of its members in leading a Christian life. It was meant primarily for medical students, by whom it was founded, as a help in the special difficulties and temptations of a medical student's life. It still also serves to keep before the mind of all who deal with the diseases of the body that highest part of man's nature which finds its expression in religion. Membership of the guild is open to students and practitioners of medicine who are communicants of the Church of England, the clergy of which are eligible for election as clerical associates. The entrance fee is 1s., and the annual subscription not less than 2s. 6d. nor more than £1. Chapters of the guild are held frequently in London, and there are wards at Cambridge and elsewhere. There are also in London a women's ward and a medical students' branch. Tickets for the service and further particulars concerning the guild may be obtained on application, accompanied by a stamped and addressed envelope, to the guild secretary,

Sir GERALD GIFFARD, I.M.S. (Madras), claimed to have put on forceps more often than anyone present, as he had lived for years on the premises of a maternity hospital where 2,500 cases were delivered annually. He felt sure that the abuse of forceps was nearly always due to faulty diagnosis. He sympathized strongly with the difficulties of the general practitioner; at the same time it was better to be safe than sorry. If they could persuade their patients to be examined before the onset of labour they would not get difficult forceps cases. He strongly advised his hearers never to be trapped into attending a maternity case where they had to put on forceps at once. It was the surprises of midwifery which created the difficulties. They should aim at securing institutional treatment for all their cases. At all costs students should be trained on the pregnant woman.

Dr. PURSLOW (Birmingham) thought that all present would agree with the opener as to the danger of the high forceps operation and the inadvisability of ever applying forceps with the head freely movable above the brim; but that, in regard to the low forceps operation, especially in cases of delayed second stage due to ineffective pains, there was room for difference of opinion, and it was interesting to see how the pendulum swung from one extreme to the other in the teaching on this point. About thirty years ago at an Annual Meeting of the Association, when he was secretary of the Obstetric Section, there was a discussion on the subject; it was opened by Playfair, who stated that when he was a student there was the greatest possible reluctance to apply forceps in this class of case, and he summed up his position in the discussion in these words: "Few, I think, will deny that unnecessary delay after the head is in the pelvic cavity is not only useless but pernicious, and that by timely interference we lessen the risk both to mother and child." He (the speaker) thought that few would now deny that since Playfair's day the forceps had been used with unnecessary frequency, but he thought Mr. Berkeley had gone too far in the direction of non-interference. He entirely disagreed with Mr. Berkeley in attributing vesico-vaginal fistula to the use of the forceps, and thought that it practically never occurred in that way, unless gross carelessness was used, but that it was almost invariably due to pressure necrosis from a prolonged second stage, and might have been avoided by a timely use of the forceps. He considered that it was very bad practice to rotate occipito-posterior positions with the forceps, and on two recent occasions when called in by practitioners on account of the advent of puerperal sepsis he had found, when he had made a complete examination under an anaesthetic, that there was a deep longitudinal tear extending the whole length of the vagina; the practitioner, in each of these cases, had rotated an occipito-posterior position with the forceps, and was quite unaware of the damage done, as it was not visible until a Sims's speculum was used. On this and other points, such as the wearing of rubber gloves, and the great advantage of having an anaesthetist present, he was in entire agreement with Mr. Berkeley. He thought it very unfortunate that the consulting obstetrician was called in, as a rule, during the puerperium when he could do little to help matters, and not during labour, when he might be of much more assistance, but the attitude of the public was largely to blame for this.

#### *Mr. Comyns Berkeley's Reply.*

Dr. Fairbairn's remarks were just as full of wit and wisdom as his always are, and I need hardly say that I agree with his appeal for preventive treatment as against operative. There is only one point upon which I would venture to disagree with him, and that is his statement that the sister midwife is the most suitable person to demonstrate normal delivery to students. If such is obtainable I think that a doctor, with adequate knowledge of his subject, is preferable.

I take it from his remarks that in the main Dr. Hendry agrees with me. I understood Dr. Ford to say that it was idealistic that students should be better taught.

I cannot agree with this. Those of us who are accustomed to teach medical students—and I have been doing so about thirty years—know that one must teach students to 100 per cent., for it is only by so doing that one can teach them enough; since they will not be likely to remember more than 50 per cent., if as much. I did not mean in address to advocate that women should only be confined in general hospitals, as Dr. Ford seemed to imply. I think the ideal method is that, if the home of the patient is unsuitable, she should be sent to some institution where she can be attended by her own family doctor, and that every town of any importance such institutions should be established. Dr. Ford seemed to me to harp too much on the fact that the saving of the life of the patient was the sum and total of all one's endeavours, whereas the principal duty of hospital teachers is to stress the importance of preventive treatment, as carried out at ante-natal centres. Then Dr. Ford found fault with my assertion that all women in labour should have the pubes shaved, and said that "would not stand it." But it is the duty of the medical profession to educate the public, and it is but rarely that the reasons are properly explained, that women will refuse to be shaved. Dr. Ford thinks that more cases of prolapse of the uterus occur after labour without the use of the forceps than with its use. The impression I have got from my experience of many years in the gynaecological wards at the Middlesex Hospital and at the Chelsea Hospital for Women does not lead me to agree with him, and I feel certain, if an equal number of cases is taken, that this is not so. He thought that the percentage of sepsis in cases of Caesarean section after the futile use of the forceps was exaggerated. Amand Routh, in his celebrated monograph on Caesarean section, including reports on many hundreds of cases, states that the mortality of Caesarean section before labour and in selected cases was 1.6 per cent., whereas after attempts to deliver with the forceps had been made the mortality was 10 to 14 per cent. I understood Dr. Ford to say that he did not think that his percentage of deaths—30 per cent. in Caesarean section after the use of the forceps or other interference—was too high, but I cannot help thinking that if this was the common experience Caesarean section would have to be banished from the list of justifiable operations.

Mr. Rivett emphasized the fact that if the students were not properly taught it was the fault of the teachers. Up to a point I entirely agree with him, though of late years many teachers have done all they could in this respect. One cannot make bricks without straw, and as long as the various examining bodies do not insist on students having experience as dressers in the gynaecological wards the teachers are seriously handicapped.

Dr. McAskie seemed to think that as a rule it was too late, when the patient was first seen, to get any information worth having from abdominal palpation. I could not have a better testimonial for my insistence on ante-natal supervision, and, moreover, it is not too late to ascertain that the head is above the brim, and that the forceps should not therefore be used, yet they are very commonly used in such circumstances. I think he misunderstood my reference to occipito-posterior positions. I did not say that all these should be rotated with the hand. On the contrary, I have been all my professional life insisting on the fact that Nature should be given every chance, and that the doctor should only interfere when she failed. It is certainly better to try and rotate an unreduced occipito-posterior position with the hands than with the forceps. He really seemed to me to be speaking of forced delivery all the time, which is absolutely contrary to what I advocate. If I understood Dr. McAskie correctly it is that I have made too much of the spectre of sepsis, and that in general practice it was not nearly so common as I seemed to infer. As a fact there is no diminution of sepsis mortality either in the United Kingdom or abroad. The statistics of childbirth deaths for 1919-20 were higher than in any other period, and in New Zealand, where the matter was taken up very strongly, it was thought that this was due to the indiscriminate use of

## SCHOOLS.

ST. GEORGE'S HOSPITAL.

MR. E. B. TUCKER'S ADDRESS ON "PRACTICE."

[Abstract.]

To do well in practice a very sound knowledge of your profession, though by far the most important, is by no means the only factor which makes for success. Personal ability, tact, sympathy, understanding, and a profound knowledge of human nature are indispensable, and you cannot commence to cultivate these essentials too early. If you, therefore, wish to do well you must become a "man of parts" in every sense of the word. For this reason I urge every one of you to have some interests outside your actual profession; cultivate some hobby. For some of your inclinations may lead you to vary your work by taking up some other line of scientific research, but those of you to whom sport in any form is a real recreation, "grapple it to your soul with hooks of steel." Play the strenuous games while you are here, so long as you may be able; afterwards harness the ball in milder fashion, play the grouse, or beguile the fish whenever you get the chance. A sporting reputation will often be of service to you in quite unexpected ways.

There are two subjects which, if you wish to do well, you must practically make a part of yourselves—anatomy and physiology. These are the twin rocks on which the whole edifice of your work, both here and in practice afterwards, is founded and built. The General Medical Council, in revising the curriculum last year, was so impressed with the necessity of a continuing knowledge of these two subjects that it enacted that the teaching of both should be continued during the whole course of professional education, and that the student's knowledge should be thoroughly tested in the final examinations, both in the anatomy of the living body and in that of the subject. Whenever you get a chance do things for yourselves. Do not be satisfied with watching others demonstrate how they should be done. Under the new regulations for examinations more value will be given for practical work; a brilliant theoretical paper will not in future outweigh bad clinical or practical work. Supplement your reading by the work of your hands on every possible occasion. I most strongly advise every one of you to set your faces steadily towards house-physician and house-surgeon under the supervision of the staff of some hospital. Not only will the experience gained from your cases and the responsibilities of a house-physician and house-surgeon under the supervision of the staff of some hospital. Not only will the experience gained from your cases and the responsibilities of a house-physician and house-surgeon under the supervision of the staff of some hospital. Not only will the experience gained from your cases and the responsibilities of a house-physician and house-surgeon under the supervision of the staff of some hospital.

I hope is still the custom here, you teach in the wards as you go round, that teaching will increase your own knowledge fourfold. The greater number of you will go out from here and start work as general practitioners, or in other words you will take up your positions in the first and front line of defence against disease and death. In London and the great industrial centres you will be the first to see the beginnings and earliest symptoms of mischief which in many cases may be but of little moment, but in others of the greatest importance. In the sparsely populated rural districts you will be even more responsible. In either case your motto must ever be "Principia obsta," and the early exercise of your intelligence and acumen will save many a life and put a term to years of unnecessary invalidism. You will have the advantage of seeing your cases when it is possible to term to years of unnecessary invalidism. You will have the advantage of seeing your cases when it is possible to term to years of unnecessary invalidism. You will have the advantage of seeing your cases when it is possible to term to years of unnecessary invalidism.

Therefore, during your preparation for future practice cultivate without ceasing the ability to make an early and accurate diagnosis, coupled with a sound prognosis, in every case you may see, however commonplace and trivial it may appear at the first glance. In the sparsely populated rural districts you will be even more responsible. In either case your motto must ever be "Principia obsta," and the early exercise of your intelligence and acumen will save many a life and put a term to years of unnecessary invalidism. You will have the advantage of seeing your cases when it is possible to term to years of unnecessary invalidism. You will have the advantage of seeing your cases when it is possible to term to years of unnecessary invalidism.

more especially, about what has not yet been found out but he hopes may yet be found out, through the application of the methods he has devised. The financial stability of the institute is still a matter of some anxiety. Sir James Mackenzie has himself been one of the most generous benefactors, and we are glad to hear that a special fund is being raised in Perthshire, his native county, to provide an endowment fund, which, it is hoped, may eventually reach £10,000. Already, it is stated, the sum of £5,000 has been received by the council of the Institute as a first instalment. Perthshire may well be proud of her son, and we fervently hope that the total aimed at may shortly be obtained.

## INEQUALITY OF THE PUPILS IN PULMONARY

### TUBERCULOSIS.

Inequality of the pupils in pulmonary tuberculosis has been recently called the sign of Roques, who, in 1873, wrote his Paris thesis on inequality of the pupils in unilateral affections of various parts of the body. In addition to the inequality of the pupils, which is obvious and is spoken of as spontaneous, there is a latent inequality which becomes visible only after a mydriatic is put into both conjunctival sacs; this inequality is spoken of as provoked. In a small monograph, appropriately from the Laennec Hospital in Paris, Dr. W. Jullien deals with this question of anisocoria in pulmonary tuberculosis and records his observations on 61 cases of unilateral disease; he found spontaneous inequality in 26 per cent. and provoked inequality in 71.4 per cent. Inequality of the pupils may be due to dilatation caused by irritation of the sympathetic caused by pleuritic adhesions near the apex of the lung, or more rarely to myosis from paralysis of the sympathetic caused by a destroying lesion. But careful analysis shows that the pupils may be unequal in the absence of any apical disease, and therefore that these explanations will not fit all cases; it also proves the error of the hope that equality of the pupils, by rendering pleuritic adhesions improbable, would be evidence in favour of a successful artificial pneumothorax. As inequality of the pupils may accompany any disease of the lung, such as pneumonia, bronchiectasis, tumour, and hydatid, it appears probable that in many instances at least the inequality is reflex through the vagus, medulla, and sympathetic trunks. Jullien divides the inequalities of the pupils into two groups: the slight and transient, accounting for most instances of this sign in pulmonary tuberculosis; and well marked inequality of the pupils, rare in pulmonary tuberculosis and found usually in syphilitic patients.

The first Victor Horsley Memorial Lecture, which is to be given by Professor Sir Edward Sharpey Schaffer, F.R.S., will be delivered in the Barnes Hall of the Royal Society of Medicine on Thursday, October 25th, at 5 p.m. The subject is the relations between surgery and physiology. The Rotherghillan Prize Committee of the Medical Society of London has awarded the Rotherghillan Medal and Prize to Sir Arthur Keith, F.R.S., F.R.C.S. The presentation will be made at the general meeting of the Society to be held on Monday next, October 8th, at 8 p.m.

The first of the museum demonstrations for this session at the Royal College of Surgeons of England will be given by Sir Arthur Keith on Friday next, October 12th, at 6 p.m. The subject is hernial formations of the alimentary canal and at other sites. *Inguinal pupillate et tuberculosa pulmonarum.* Par le Docteur W. Jullien. Paris: Anais Legrand, 1923 (Roy. Soc. Med. 2 plates, 13 figures).

This case, judging from the amount of the hæmorrhage, would be considered a severe one. The sedative effect that the injections had on the child was surprising; they were followed in each instance almost immediately by profound slumber. The essential cause, in this instance, as in the largest number of cases of "the hæmorrhagic disease of the newly born," was obviously the lack of some substance in the blood essential to coagulation.

Newport, Mon.

## MANIPULATIVE SURGERY.

On October 2nd Mr. R. C. ELMSLIE delivered his presidential address, on manipulative surgery, before the Orthopaedic Section of the Royal Society of Medicine.

The use of manipulative methods, he said, was becoming increasingly prominent. Because it could easily be acquired and could be carried out with little training, and was largely immune from gross accidents, it was frequently taken up by unqualified practitioners. Formerly such men were called "bonesetters," and claimed that by manipulation they replaced small bones. The term "bonesetter" was an ancient one, and was applied formerly to regular and irregular practitioners. In the seventeenth century there was a "bonesetter" and an "assistant bonesetter" on the staff of St. Bartholomew's Hospital; both were presumably surgeons. Recently the irregular practitioner had become known as a "manipulative surgeon" rather than as a "bonesetter." X rays had made the claim to replace small bones difficult to sustain. The osteopaths, rare in this country but common in America, still used this method of describing their work. They did this in spite of radiography, relying upon the comparatively complicated osteology of the spine. Sir James Paget investigated bonesetting, and published a clinical essay upon it in 1867. Howard Marsh followed his teaching, and recorded his views in the following succinct paragraph:

"Chirurgery, or handicraft, began, as we may well believe, in attempts to pull-in dislocated bones, to straighten distorted joints, and to restore movement to stiff limbs. In this dawn of the nothing was known of anatomy or pathology; it was only that a limb was bent or stiff, and force was employed to overcome the defect, just as it might be used to straighten a crooked bar, or loosen a rusty lock. Soon, however, the primitive operators of those early days became ranged in two groups: the mere empirics, who went straight to the point of trying what force would do; and those who endeavoured to ascertain the nature of particular cases and the difference between one case and another—those, in other words, who cultivated pathology and diagnosis in order that they might use force with safety and advantage. The results of practice conducted on these different lines can easily be imagined. The empirics, applying force in all cases alike, and thus involving their patients in a mere game of chance, did good whenever such untampered force as they could use was appropriate, and harm whenever it was unsuitable; those who used force only when they could see a reason for doing so, and when they thought it was safe, while they did little harm, and often, as their diagnosis was very rudimentary, missed an opportunity of producing a cure. In these conditions the empirics frequently had the best of it. Regular, but as yet very ill-informed, practitioners were so often beaten in their encounters with disease that they lost credit in the public eye; while the empirics, making the most of their cures, and not seldom laying the blame of their failures on the surgeon whose previous treatment they alleged had done all the mischief, were accredited with powers that approached the miraculous. And we can understand their success, for every surgeon now well knows that instances are common enough in which pain and limited motion, resulting from sprains and other injuries, may at once be set right by even rough and unskilled movements, or, indeed, by an accidental wrench."

Better methods of treating injuries, together with the evolution of a well trained and experienced school of massage, had lessened the number of cases of gross stiffness of joints after injury, the class of case most often quoted by Paget, Marsh, and Wharton Hood. In spite of these improvements unqualified manipulators still appeared to be in some cases dramatically successful. The medical profes-

sion should look to its methods and inquire why so many of these cases passed into unqualified hands.

Certain factors favoured the irregular practitioner. The public tended always to believe in some peculiar ability in methods of manipulation possessed by the "bonesetter" and denied to the profession, or in an almost occult power of seeing what was wrong inside a joint. Moreover, the unqualified manipulator could advertise either directly or through the mouths of his patients. A third factor, and perhaps the most important, was the fact that the failures of the irregular practitioner were almost always hidden. The patient whom he cured boasted of the fact; the patient whom he failed to cure, or made worse, was perhaps somewhat ashamed of his credulity, and kept silent on the matter. The failures of the irregular manipulator were very many. Marsh mentioned two cases of sarcoma and one of spinal caries treated by manipulation. Such gross cases were perhaps becoming rarer, but Mr. Elmslie himself had seen a patient with myositis ossificans around the knee rendered so ill by the manipulation of a bonesetter that complete rest of the joint for two and a half years was necessary; a youth with slight spinal injury rendered a confirmed neurasthenic with coccydynia through manipulation of the coccyx; a young woman converted by osteopathy into an apparently hopeless neurasthenic; and a large loose body in a knee so manipulated that it blocked full extension for four years. Moreover, cases of obvious fraud could be quoted: a joint with bony ankylosis had been treated by manipulation for a year, the patient being promised a restoration of mobility; a dislocated thumb was treated for three months with improvement of movement in the direction of excessive hyperextension; and a normal shoulder was stated by a bonesetter to be dislocated. In this last case it appeared that the bonesetter, confronted with an x-ray photograph showing the joint in place, countered with a radiogram of a dislocated shoulder which he stated was normal.

Errors of omission in which the unqualified practitioner had stated that the condition was outside his province were common. Such patients were often cured by a simple manipulation by a medical man. In addition, cases in which manipulation had failed to cure or in which the trouble had recurred were in the experience of many. Often in these cases the bonesetter was not to be blamed for failure. If the patient had any justifiable complaint it was because a certain cure had been promised where no certainty was possible. But when failure was due to insufficient care in diagnosis or to inadequate knowledge of pathology, or to the use of irrational methods, the manipulator should be blamed.

All medical men had their failures. The real interest of the profession, and particularly of the orthopaedic surgeon, was to frame such rules of treatment as would leave as few cases as possible for the unqualified manipulator to treat.

Looking back upon his own practice, the speaker ventured to make the following suggestions. It was most important that in treating all bone, joint, and muscle injuries, as accurate a judgement as was possible should be made upon the pathology of the condition. If there was inflammation present, or any condition indicating rest and contraindicating mobilization, let them say so. If there were right the patient would never be cured by any practitioner taking the opposite view. They should remember the common error of assuming that the inflammatory reaction to a simple injury indicated rest. That was not so. A sprain, providing that an important ligament was not ruptured or unduly stretched, recovered most rapidly with normal use. If necessary the joint should be supported. An injury to a small portion of muscle required as soon as pain would allow. In cases of damage to displacement of the internal semilunar cartilage of the knee the joint should be used as soon as possible after the displacement had been reduced. Some years ago he treated an oarsman in training for an important race who displaced the internal semilunar cartilage nine days before the race. The displacement was reduced twelve hours after the injury. The patient was only kept out of his boat for twenty-four hours, and finally rowed with an apparently normal knee. He had had no trouble since.

## MIDDLESEX HOSPITAL.

The opening of the winter session of the Middlesex Hospital Medical School took place at the Scala Theatre on October 2nd, when the Earl of Athlone presided, and Princess Alice, Countess of Athlone, presented the prizes to the students and nurses. An address, accompanied by the lantern, was delivered by Mr. Somerville Hastings, F.R.C.S., on "Team work in nature."

Mr. Hastings cited numerous examples, such as bees, ants, corals, migrating birds, to show how much team work there was among creatures of the same sort, but he went on to describe how plants and animals of different kinds also co-operated, how, for example, plovers lived with crocodiles, and sea anemones with hermit-crabs, to the advantage of both, how tiny seaweeds lived in the interior of marine worms, each party to the "contract" gained by the association, and how the pollen of flowers was carried by insects. He spoke in particular detail of fungi, describing some recent investigation on the team work which was carried on by these lowliest of plants in association with other plants and animals. The lichen, for example, was really a dual organism, composed of a fungus united with a green plant (an alga), and both constituents benefited from the alliance; the alga obtained water and mineral matters collected from the soil by the fungus, and the fungus obtained carbon products which the alga collected from the air by the aid of light. Nearly all flowering plants had fungi associated with them at some stage of their life history. Many tropical fungi, again, showed an unmistakable adaptation for the dispersal of their spores by insects, or by things which ate the plant. Mr. Hastings concluded by applying his subject as a parallel to the team work in the wards of the Middlesex Hospital, where physicians, surgeons, sisters, and nurses, not to mention the humble specialists, united in the single purpose of healing the sick.

The Dean of the School (Mr. A. E. Webb-Johnson), in a brief report of the year's work, after a reference to the losses sustained during the year, and to the honours gained, spoke of the additions which have been made to the Bland-Sutton Institute of Pathology during the year. The Council of the School decided early in the year to increase the accommodation for pathological research. A new top story was therefore added to the new building which had been put up in 1914-15, and this furnished accommodation for secretarial offices, a library, a large laboratory for public health work, and two smaller research laboratories. The building now consists of four stories, the three lower ones containing a museum, a lecture theatre seated for upwards of 160, and two large teaching laboratories with 70 working places.

After the prizes had been presented a number of complimentary speeches were delivered by Sir John Bland-Sutton, Dr. C. E. Lakin, Mr. Sampson Handley, and others. Mr. Webb-Johnson expressed his great regret that of his office as dean. It was no disparagement of his predecessors to say that Mr. Webb-Johnson's work would be critical stages in the history of the School for generations. At a founder, Sir Charles Bell, in his most imaginative moments could hardly have thought to be possible. He had provided them all with an object-lesson of what could be done, even in difficult circumstances, by having a wide outlook, a discriminating judgement, a respect for tradition, and the will to strive until a worthy purpose was attained.

## CHARING CROSS HOSPITAL.

The winter session of the Charing Cross Medical School was opened on October 3rd with the distribution of prizes by Dr. William Hunter, C.B.

Addressing the students, Dr. Hunter spoke of the romance connected with medical studies. This was a feature not very obvious to the student himself. The amount of knowledge he had to acquire was stupendous, ten times greater now than it was twenty years ago. Yet the

## KING'S COLLEGE HOSPITAL.

The opening of the ninety-fourth winter session at King's College Hospital Medical School took place on October 3rd, when the prizes were presented by Mr. H. J. Waring, F.R.C.S., Vice-Chancellor of the University of London.

Viscount Hambleden presided.

The Dean (Dr. Williamson Tyte), in reporting on the work of the school, said that at the present time there were 244 unqualified students in residence; of these 94 were women; 97 were working at the preliminary and intermediate courses at King's College and elsewhere, and 147 were pursuing their final studies at the hospital. In the medical school there were also 44 qualified students who were preparing for higher qualifications and degrees. Much of the success of the school during the past year had been due to the carefully organized teaching and to the energies of the whole-time experienced clinical tutors in medicine, surgery, and midwifery. He regretted to state that there were still something like a hundred beds closed to the public through lack of hospital funds.

Lord Hambleden thanked the students for the assistance which they had given on various occasions in raising money for the hospital. The greatest development at King's College Hospital which was being undertaken to-day was the establishment of a dental school. Dr. A. Livingston had been appointed director of dental studies and had been working very hard for some months on its organization and equipment, and he hoped that before long the school would be ready to receive students and afford treatment to out-patients. Every facility would be given to the students of

no other profession contained.

Dr. Hunter went on further to speak of the era of anti-toxin and protective inoculation, and of other great recent advances, and then turned to consider the object of medical education. This was not merely to acquire knowledge, but to train the faculty of observation, and for this purpose no class of education was better adapted than daily contact with patients. To emphasize unduly the importance of laboratory methods at the expense of clinical observation was disastrous alike to the patient and to the great science of medicine. Having spent the whole of his professional life with one foot in the wards and the other in the laboratory, he would say that if the alternatives were placed before him of seeing the laboratory reports or seeing the patient, he would rather base his diagnosis, prognosis, and treatment on his own bedside observations than on any series of laboratory reports, however detailed. At the same time he urged the students to make themselves fully acquainted with the meaning and the value of the laboratory method. In conclusion, he said that medicine offered a career of glorious adventure, and carried with it a human interest such as

medical student had great consolations, chief among them the interest of his studies, in particular the great problem of disease, the variety of forces marshalled for the attack against health, and still more wonderful variety of forces which the body marshalled in its own defence.

Dr. Hunter proceeded to set forth the stages in the advance of medical knowledge. First came the era of clinical medicine, when the symptoms and main characteristics of the different diseases were recognized. The second great stage, commencing about 1850, was the era of morbid anatomy; the third, the era of bacteriology; the fourth (on which he spoke at some length) the era of surgical sepsis and antiseptics. At first the subject of sepsis appeared to be confined to the realm of surgery, but during the last twenty years a silent revolution had been brought about in the general view with regard to the importance of sepsis in medicine. The removal of the foot of septic infection in medical cases had been followed by results often as striking as those met with in surgery. One great point of practical interest in this development was that the seat of the sepsis referred to was connected in the great majority of cases with a region of the body most accessible to treatment—namely, the teeth and their sockets. The subject of oral sepsis should be of special interest to the students of that school, because it was from Charing Cross

inferences and opinions "facts" has been one of the curses of science. We should all be the better for a severer discipline in verbal accuracy, even Mr. Ritchie. Lord Riddell, in his bright little book *Some Things That Matter*, sharply corrects this very error, rebuking those who describe inferences as "facts," and mistake inferences for facts. The witness-box is an admirable school for doctors of all faculties.

Under the head of teleology is not something wanting? Mr. Ritchie deals with the idea rather diffusely, but only with the faded misconceptions of a pre-existing mould or type or contrivance. But there is a returning inclination to a teleology of some form other than those outworn, narrower, and empirical notions; something architectonic, such as, in the gradual phases of the past, has marshalled the forces for the construction of a crystal or a brain; something, for instance, that governs the collections and troopings of cells as they sweep into orderly ranks, gathering together from parts near and remote as if animated by a common purpose, guided by an unseen wand each to its own group, for the construction of this part or organ or that; materials not blindly shaken into any sort of shape, but themselves seeming to foresee and conspire to some larger end.

C. A.

### AVITAMINOSIS.

Dr. J. LOPEZ LOMBA has published an interesting critical study of certain aspects of the vitamin problem supplemented by an account of his own original work. The monograph is entitled *Etudes expérimentales et critiques sur l'avitaminose*.<sup>2</sup>

The author begins with a comparative study of the vitamin needs of various forms of vegetable and animal life, and goes on to discuss the needs of the lower forms of vegetable life, and particularly the needs of bacteria and fungi, for minute quantities of thermolabile substances. A great deal of work has been done on this subject, and the number of such substances described in the case of pathogenic bacteria threatens to exhaust the alphabet. Unfortunately the whole subject is in a very obscure state. The best established of such factors is the organic substance stated to be essential for the growth of yeast. Evidence for such a substance was first revealed in the celebrated controversy in 1870 between Liebig and Pasteur on the subject of spontaneous generation. In 1901 Wildiers definitely described an organic substance, which he named "bios"; it was, he said, essential for yeast growth. In the last few years many attempts were made to identify "bios" with vitamin but these attempts failed, and recently Nelson, Nor, and Cessna have produced strong evidence how that yeast does not require for its growth presence of any organic substance which the yeast cannot themselves synthesize. The very uncertainty yielded by this prolonged controversy indicate how incomplete is our knowledge concerning the part played by vegetable life by substances having an action in any analogous to that of the vitamins essential for elaborate life.

Dr. Lombas also summarizes existing knowledge concerning the needs of invertebrates for vitamins, but in case also the evidence is very incomplete and often radiatory. A good classified bibliography is given, however, and this should be of great value to those interested in these problems, since the vitamin literature is so extensive that it is very difficult to obtain information concerning the work done on any particular problem. The author gives a fairly full account of our knowledge concerning the comparative needs of different vertebrates for vitamins, although no reference is made to some of the work that has been done upon farm animals. The comparison of the vitamin needs of vertebrates brings out very curious and inexplicable facts. For example, pigeons, as said, resist deprivation of vitamin A indefinitely, but such deprivation kills fowls within two or three days. The guinea-pig is killed by lack of vitamin C in

a few weeks, whereas the adult rat and rabbit resist indefinitely. The comparisons set forth are highly interesting and the work is particularly valuable, because this aspect of the vitamin problem is rather neglected by most books on the subject.

The chief original work done by the author has been the study of the changes of weight produced by vitamin lack in the different organs of the body. He deprived large numbers of pigeons and guinea-pigs of vitamin I and studied the progressive changes in weight of the various organs from the commencement of vitamin deprivation until death. The curves obtained are very curious for many of the organs show extraordinary fluctuations in weight. The suprarenals, for example, at first lost weight and later, in the last week of life, underwent great increase; on the other hand, the testicles, pancreas, thyroid, and spleen at first gained in weight and then lost weight rapidly during the last few days of life.

The changes observed in the guinea-pig do not altogether agree with those observed in the pigeon, but the facts brought forward show that the weights of the different organs observed after death from vitamin deficiency give little evidence as to the preceding changes during the progress of the deficiency process. From these curves and from other facts the author concludes that the symptoms physiological disorders, and pathological lesions observed in avitaminosis are, above all, dependent on functional derangements of the vegetative nervous system, produced by the lack of vitamins. That is to say, he believes that the essential effect of vitamin lack, and particularly a lack of vitamin B, is disorganization of the sympathetic and parasympathetic systems, associated with a disturbance of the functions of the endocrine organs, and that these disturbances produce the symptoms and lesions observed.

Thus, in a single bold effort of the imagination, the author links up avitaminosis, sympatheticonia, parasympatheticonia, and endocrine deficiency. The idea is audacious, but the facts established concerning all these subjects are so incomplete that it is doubtful whether such a comparison is likely to advance our knowledge materially.

### TONSILS.

The importance which the pathology and surgery of the tonsil have assumed in recent years is reflected in two admirable monographs setting forth the views of the Boston school and the St. Louis school. The first of these is already well known, for Dr. BARNES established his reputation by a previous edition of his book on the *Tonsils*,<sup>1</sup> nine years ago. In the second, Dr. SLUDER has gathered into a well illustrated volume everything that there is at present to be said on the subject of *Tonsillectomy*<sup>2</sup> by means of the guillotine.

The anatomy, embryology, general physiology, and pathology of the tonsils are well reviewed in the opening chapters of both these works. In this part of the subject there is but little that is controversial, but none the less there is somewhat speculative, so that it is difficult to give a clear exposition. The authors, however, have been highly successful. It is when the subject of the surgery of the tonsil is reached that the great divergence of opinions is to be found, though on one essential point they are unanimous—namely, the necessity of complete removal.

Dr. Barnes describes fairly and adequately the various methods of removing tonsils, but he states that he always dissects tonsils himself "for the reason that good technique cannot be maintained if the operation is only done occasionally, and a certain number of tonsils must be removed by one of the dissection methods." This is a logical position, but the reason given for performing a more severe operation in all cases, when in most of them the quicker simpler operation of Sluder is sufficient, is inadequate. Dr. Barnes advocates the drainage of quinsy by removal of the tonsils. No doubt the drainage provided by this

### MANCHESTER POST-GRADUATE COURSES.

A FREE course of lectures will be given alternately at the Salford Royal Hospital and Ancoats Hospital, Manchester, on Thursdays at 4.30 p.m. The subject of the first course will be "Surgical tuberculosis," and the lectures will begin on Thursday, October 18th. The intention is to get away from the usual style of post-graduate lecture, and for this reason a definite subject will be taken up for consideration. The lectures will be illustrated by lantern slides, pathological specimens, demonstrations of clinical cases, etc. The titles of individual lectures will be announced in the weekly diary published in the *STREMER*. A free course of lectures of similar scope will be delivered after Christmas by the physicians of the two hospitals on a subject which will be announced later.

### POST-GRADUATE COURSES IN LONDON.

The Fellowship of Medicine and Post-Graduate Medical Association has arranged a fortnight's intensive course in children's diseases, consisting of clinical demonstrations in all departments, to be given at the Victoria Hospital for Children from October 8th to 20th. A special course in laryngology, rhinology, and otology will also take place at the Central London Throat, Nose, and Ear Hospital from October 8th to 26th. Clinical lectures and demonstrations in the wards and out-patient department will be given each day from 9.30 to 5 p.m. From October 15th to 27th two short courses will be given in cardiology at the National Hospital for Diseases of the Heart, and in proctology at St. Mark's Hospital for Diseases of the Rectum; both courses will include clinical lectures and demonstrations by members of the staff each day. A short course in dermatology will be held at the Hospital for Diseases of the Skin, Blackfriars, from October 29th to November 10th. The next fortnight's "refresher" courses in general medicine and surgery will be given by the Royal Northern Hospital, in conjunction with the Central London Ophthalmic Hospital, the North-Eastern Fever Hospital, and the Royal Chest Hospital, from November 5th to 17th. Copies of the syllabus and full particulars regarding the above courses can be obtained from the Secretary to the Fellowship of Medicine at 1, Wimpole Street, W.1. As the numbers are limited for some of the courses early application should be made.

**SHEFFIELD ROYAL INFIRMARY.**  
The new x-ray department of the Sheffield Royal Infirmary was opened by the Lord Mayor of Sheffield, Alderman Denton, on September 26th. Mr. H. H. Bedford, the chairman of the board, who presided, said that with the increase in the work of the radiological department the board were very anxious to re-house it, and the Orthopaedic Committee had given them £2,000 for this purpose, an old member of the board, Mr. Huntsman, had also promised £500 towards the building. The board had been further encouraged that morning by receiving a cheque for £500 from Mr. Dixon Hallam, who is in charge of the radiological department, described the new apparatus and gave a brief survey of the development of radiology. The first apparatus had been installed in the Infirmary in 1899, but while it had been improved year by year it had also become very expensive. It was now necessary to have three rooms, each with a separate equipment to cope with the work; both out-patients and in-patients were passing through the department all day long, necessitating a whole-time staff of four persons. In designing the new department the first consideration had been the safety of the staff and patients. The control room was completely lined with thick sheet lead, and the very best apparatus had been installed.

**SURREYAN ROYAL INFIRMARY: NEW THEATRE BLOCK.**  
On September 26th the family in memory of the late J. X. Short, Esq., J.P., shipowner, at a cost of £7,000, was opened and equipped by his family in memory of the late J. X. Short, Esq., J.P., shipowner, at a cost of £7,000, was opened

## Scotland.

### CENTENARY OF THE MORISON LECTURES.

The centennial course of the Morison lectures on mental diseases and disorders in the Royal College of Physicians, 1833, will be delivered in the Morison system, founded in Edinburgh, on Monday, Tuesday, and Wednesday, October 15th, 16th, and 17th, at 5 p.m., by Dr. Alexander Blackhall-Morison. The titles of the lectures will be respectively: A century of neurology—the instrument of mind; A century of psychology—the mind diseased. psychiatry—the mind diseased.

### THE CHAIR OF MEDICINE AT ST. ANDREWS.

Dr. Adam Patrick has been elected by the University Court of St. Andrews to succeed Professor Stalker in the chair of medicine in the University of St. Andrews, and the directors of the Royal Infirmary, Dundee, have appointed him an honorary physician. Dr. Patrick, who is at present assistant to the professor of medicine in the University of Glasgow, was educated at that University, and graduated M.A. in 1904, M.B., Ch.B. in 1908, and M.D. (Bellahouston gold medal) in 1913. He holds the appointment of dispensary physician to the Glasgow Western Infirmary, and was formerly consulting physician to the City of Glasgow Fever Hospital and visiting physician to Bellahouston Hospital, Glasgow. During the year he held a commission in the R.A.M.C., and was for three years a specialist in bacteriology in Malta. He was honorary secretary of the Section of Medicine during the annual Meeting of the British Medical Association at Glasgow in 1922. The St. Andrews University Court, in accepting Professor Stalker's resignation, has placed on record its high appreciation of his distinguished services during twenty-five years' occupancy of the chair.

### NEW PROFESSORIAL CHAIR AT GLASGOW.

Until now the work in forensic medicine and public health in Glasgow University has been carried on in one department as one professorial chair. With the great advances of recent years in public health and preventive medicine, the creation of a new chair in these subjects has become necessary. The institution of this chair has been under consideration for some time, but through the generosity of Mr. Henry Meehan it has now been established, and will be known as the Henry Meehan Chair of Public Health. The University Court of Glasgow has appointed as its first incumbent Dr. John Ronald Currie, at present Professor of Preventive Medicine in Queen's University, Kingston, Ontario—a post he has held only a few months.

instance Mrs. Scharlieb's statement that "each young couple should exchange medical certificates of health and of fitness for matrimony," and Mr. C. J. Bond's suggestion that "the nation requires child fanciers more than dog fanciers, and home-culture as well as horticulture and agriculture."

The "sex problem" occupies much of the attention of the authors of this book. In this case also there is some divergence in the views expressed in the various essays. Thus, in the opinion of Sir Frederick Mott, "it is a mistake to lead the young child, as a general rule, too far into experiences that the adult alone can understand and appreciate in their full biological significance." Professor J. Arthur Thomson, on the other hand, thinks that "there is much to be said for sound biological training," and that "the functions of sex and reproduction should be discussed in the physiology class in the higher school just as frankly and detachedly as the functions of secretion and respiration." At the same time the professor notes that no one can be sure on *a priori* grounds of the results of a course of instruction in sex hygiene in the higher forms in school. "It is a matter for experiment, and the basis of experiment is not as yet large. . . . When sex instruction becomes intimate and personal there is a risk of bringing sex feelings into the focus of consciousness prematurely." Mr. Bond goes further than his collaborators and says that "we must entrust the duty and privilege of giving advice and instruction on these vital subjects [that is, sex matters] to carefully selected and properly trained teachers or other suitable persons."

Several of the writers mention "self-expression" and "self-realization" as the true aim of life, and the Rev. R. C. Gillie asserts that the trend of enlightened education in recent years has been unmistakably in the direction of emphasis on personality. Whether self-realization is the aim of life, or whether greater happiness is to be found in a life of discipline and duty, is a matter for the philosophers; but Mr. Gillie suggests that "when personality has been developed, it may easily be perverted through lack or neglect of right channels of expression." "Some people," he adds, "are obsessed already by what has been called the fetish of self-fulfilment."

Sir James Yoxall writes an interesting little essay on the future for elementary education. He sees no prospect of the school segregation of classes in the community passing away during the present generation, but he looks forward to a dignifying, magnifying, and glorifying of the name and mission of the elementary school.

From the trend of the ideals of the writers in this volume it may be inferred that nearly all of them would view with equanimity a much larger control of the individual by the State than exists at present.

#### DENTAL TEXTBOOKS.

In the training of the dental student two main lines of thought are apparent. On the one hand dentistry is regarded as an essentially mechanical art and the great object is to train the student's fingers; on the other hand, the mechanical is regarded as subservient to the biological factor and every effort is made to teach the sciences of life and death, of physiology and medicine, and to train the powers of observation. The four years' curriculum seems but a short time, yet the teacher must teach. A perception of the difficulties both of the student and teacher has induced Mr. Curzon-Miller to attempt a *Physiology for Dental Students*.<sup>1</sup> It is written avowedly with an eye to the L.D.S. examination, and "while modern and generally accepted facts of the subject have been stated somewhat dogmatically, speculative discussions have been intentionally omitted." Quantity is thus greatly diminished, but quality suffers sadly. The charm and mental stimulus of a well stated argument are entirely lost, and sometimes, as in the sole brief reference to clefts of the palate (p. 13) or in the definition of absorption (p. 53), brevity has gone so far

that the statements may appear meaningless to the student. If, however, to those whose teaching was conducted in a more leisurely fashion this volume seems to savour somewhat of the cram-book, the author must be given credit for having by judicious selection and elimination compiled a handbook of physiology which will not only suffice for the needs of the L.D.S. examination, but will help the student to understand many otherwise obscure statements in current medical and dental literature. In this latter respect we may, perhaps, make one or two suggestions. The dental student probably, in common with the medical student, would like to know how largely, in the physiologist's opinion, uric acid bulks as a factor in human health or disease; and the dental student, at least, would like to know his (the physiologist's) views as to the influence of thyroid, parathyroid, or other ductless gland, on the formation of the teeth. On these points the author might well depart from his accustomed brevity in his next edition.

Mr. Gibson's *Chemistry of Dental Materials*<sup>2</sup> is largely an elaboration of notes of lectures delivered to the dental students of Guy's Hospital, and, as it is intended only as an introduction to the more specialized literature of the subject, the author has limited himself to representative materials. To describe adequately the large and increasing number of substances available in dental practice would, the author says, require a comprehensive dictionary. Lest any dental student should thereby be terrified, we hasten to say we do not agree. The chemistry needed by a dental student can be, and should be, presented to him in comparatively small volume divested of that curious tendency to magnify and mystify so often apparent in dental education. The present volume seems, indeed, to cover the ground pretty thoroughly. It contains chapters on the general properties of metals; on platinum, gold, silver, copper, aluminium, mercury, zinc, tin, lead, iron, nickel, cadmium, antimony, bismuth, and their alloys; on porcelain, plaster-of-Paris, dental cements; abrasive material; anaesthetics and antiseptics; rubber, vulcanite, and gutta-percha; with a short introductory survey of the materials and their uses. We may say at once that the work is generally of a very high standard, and, despite the author's prefatory warning, we detect no important omission. Perhaps we may be forgiven for asking how it shall benefit the dental student to learn, even in outline, the methods of extraction of metals from their ores—there are surely matters of more immediate concern to which his mind might be directed! While, however, the general standard is high, the book in places betrays its origin in amplified notes. Page 27 may be cited, and the description given there of a eutectic alloy particularly. The assertion that vulcanite is such a poor conductor of heat that the constant wearing of a vulcanite plate in the mouth causes a lowering of vitality of the soft tissues and an excessive resorption of the hard tissues is unconvincing. The note on the soldering of platinum takes no account of the common practice of soldering gold "backs" to the platinum pins of "pin-teeth" with gold solder. Perhaps the best chapter in the book is that on anaesthetics and antiseptics; it alone is a sufficient recommendation of the book.

#### NOTES ON BOOKS.

THE textbook on experimental bacteriology and infectious diseases by Professors W. KOLLE and H. HETSCH of Frankfurt, which has now reached its sixth edition<sup>3</sup> and has been translated into French, Italian, Spanish, and Russian, consists of two volumes covering an enormous field. The work is divided into seventy-six lectures, of which the first fifteen are introductory and deal with microscopical technique, the morphology and biology of micro-organisms, disinfection, immunity, anaphylaxis, and serum diagnosis and treatment,

<sup>2</sup> *Die Experimentelle Bakteriologie und die Infektionskrankheiten mit besonderer Berücksichtigung der Immunitätslehre. Ein Lehrbuch mit besonderer Berücksichtigung der Immunitätslehre. Von Professor W. Kolle und Professor H. Hetsch. Sechste umgearbeitete Auflage. 2 Bände. Berlin: Urban und Schwarzenberg. 1922. (Double cr. 8vo. Band I, pp. xviii + 636; 41 plates, 79 figures. Band II, pp. xi + 1376; 73 plates, 135 figures.)*

<sup>3</sup> *Physiology for Dental Students*. By A. G. Curzon-Miller, B.Sc., L.M.S.S.A. (Lond.), F.C.S. (Lond.). E. Arnold and Co. 1922. (Demy 8vo, pp. viii + 205; 81 figures. 10s. 6d. net.)

Incidence according to Size of House.

| No. of Cases. | Per Cent. | Percentage of Population Living in Houses of Sizes Quoted. |
|---------------|-----------|------------------------------------------------------------|
| 1,135         | 17.95     | 2.9                                                        |
| 3,121         | 49.53     | 46.5                                                       |
| 581           | 9.11      | 21.0                                                       |
| 556           | 8.41      | 16.0                                                       |
| 465           | 7.15      |                                                            |
| 6,739         | 99.83     |                                                            |

The indication of this table is that nearly 15 per cent. of the population living in one-apartment houses contributed nearly 18 per cent. of the cases, while 21 and 16 per cent. of the population living in three- and four-apartment houses contributed 16 and 8 per cent. respectively. Approximately one-half of the population living in two-apartment houses supplied one-half of the cases. The fact that a smaller proportion of the population living in one-apartment houses should contribute twice as many cases of phthisis as a larger percentage of the population living in four apartments and that the size of the house does play some part towards producing mass infection and increased incidence.

The extent of this, however, can only be measured when corrections have been made for age and sex distribution, and a rearrangement of the figures given on page 20 of the paper already referred to shows that while the death rate from all causes in four-apartment houses equals 50 per cent. of the deaths occurring in one-apartment houses, the phthisis deaths in four-apartment houses form only 32 per cent. of those occurring in one-apartment houses. Is it not reasonable to attribute some part of this relatively greater incidence of phthisis in one-apartment houses to the element of mass infection which Dr. Walker is considering?

| Calculated Death Rates. | Taking 1-Apartment Rate as 100. |
|-------------------------|---------------------------------|
| 4.1 Cases. Phthisis.    | All Cases. Phthisis.            |
| 23                      | 100                             |
| 17                      | 85                              |
| 15                      | 65                              |
| 10                      | 50                              |
| Four apartments         | 32                              |
| Three apartments        | 45                              |
| Two apartments          | 72                              |
| One apartment           | 100                             |

MEDICAL PRACTICE IN NORTH AMERICA.

The result in this case fully supports the clinical value of this new blood test reported in some 156 sera examined including those from obscure abdominal cancers, non-mucinous, and normal) published by Dr. Shaw-Mackenzie,<sup>1</sup> and noted in a further series of 53 cases.<sup>2</sup> In a more recent series of 32 cases, similar results have been obtained. Up to the present time, in a total of 221 sera examined, the method has proved correct in 212, or 95·5 per cent. The errors were associated chiefly with diabetic, tuberculous, rheumatic, and febrile conditions. These difficulties met with were indicated in the first published series.

My object is to draw attention to the usefulness of this method, by which it has been possible to differentiate cancer of internal organs from other non-cancerous conditions in the majority of cases, and in obscure cases to exclude the presence of cancer. Most of these blood test results I have discussed myself in the laboratories at King's College during my last two and a half years, a line of promising research to which I drew attention in the British Medical Journal of February 25th, 1922.—I am, etc.,

W. J. STURSON, M.D., F.R.C.P.,  
Professor of Hygiene, University  
of London, Kings' College.

London, W., Sept. 28th.

SM.—The "Note on Medical Practice in North America," by Dr. H. Cecil H. Bull (September 22nd, 1898), has awakened in me a sympathetic chord, for I, too, now the North American continent at first hand and now in full support all Dr. Bull has to say regarding medical education in those great countries. My experience of Canadian methods of teaching the medical student is contrasted with Memorial Hospital and the General Hospital. Both institutions offer unrivalled opportunities for the clinical work, but one could not but be surprised at the absence of students from out-patient clinics and "receiving rooms," while at lectures and surgical demonstrations students crowded in.

At the General Hospital, Montreal, there is an excellent fracture clinic," in charge of a surgeon who gained his first experience with Sir Robert Jones at Liverpool, and is an enthusiast over his work, yet even here the quantity of students attending was remarkable.

So far as the Western States of the Union, and the Prairie provinces and British Columbia in Canada, are concerned I must say that the average general practitioner has a long way ahead of his prototype in this country. And the reason of this, in my opinion, is the system of "open" hospitals that prevails in those parts. The hospitals there are open to every registered medical man, who can send patients, both medical and surgical, into these institutions, and can do his own surgical work there. The result is, while one naturally practices across some poor operators, and the majority of general practitioners tackle all operations, and tackle them well. No doubt this system of the "open" hospital has its disadvantages, but it does the general practitioner a great deal of good, in that it gives those with surgical leanings every opportunity to perfect themselves in the science and art of surgery. Not so in England, where our pernicious system of staying out hospital is not always productive of the best surgical—and medical—talent.

*Lancet, 1922, ii, 729.  
 'Med. Press and Circ., 1923, i, 2.*

themselves to prolonged operations without anaesthetics, and by the enterprise and manual skill of the operators. The ordeal was severe and it is not surprising to learn that often a week passed without any operation at one or more of the great hospitals. We find, for instance, that there were no operations at Guy's, St. Thomas's, and the Middlesex Hospitals in the last week of 1823.

Bleeding was still in full vogue. Every insensible person and everyone having any symptom of inflammation or fever was in danger of phlebotomy. Nobody questioned its efficacy. In the *Pickwick Papers* we read of how when the rival Eatanswill journalists were engaged in violent personal strife, "Ben Allen and Bob Sawyer had done nothing but dodge round the group, each with a tortoiseshell lancet in his hand ready to bleed the first man stunned." Also, when Mr. Winkle fell upon the ice, Mr. Allen strongly urged him to allow himself to be bled. Sir Astley Cooper, in his lectures on injuries of the head, advised bleeding, although he warned his pupils against it in case of concussion, when the pulse was feeble or slow. In the *Lancet* is described the case of a woman who had been run over and crushed. She had a ruptured liver and the usual profuse internal haemorrhage. Yet the apothecary who was called to the case bled her. A few years later we find a note about a man with a severe scalp wound who had lost a lot of blood. He was bled at once to the amount of eighteen ounces. But he recovered nevertheless.

The editorial articles of the *Lancet* bristled with personalities, and most of those who were denounced were labelled with nicknames which to-day seem somewhat puerile. The members of the staffs of hospitals were generally called "Bats," and any mistakes that they made were shown up in articles with such headings as "Blunders by Bats."

Travers of St. Thomas's was accused of having "haggled through the limb" in amputating below the knee. The patient was reported to have said to the operator, "I think, Sir, your tools are blunt!" Rival medical journalists also came in for abuse, especially Roderick Macleod of the *Medical and Physical Review* and James Johnstone of the *Medico-Chirurgical Review*. Macleod was later physician to St. George's Hospital and quite a worthy person, but he was referred to in the *Lancet* by many rude names, such as "Charity Roderick," "Blundering Blockhead," "The Yellow Goth," and his paper was called "The Yellow Fungus" and "The Exerescence," and the question was asked, "Was the editor of the *Exerescence* drunk when he perused or wrote this sentence?" He was accused of being a literary hack and the hireling of a bookseller in the following passage:

"This glandered, foundered spavined old hack is now we hear in the stables of Mr. Ormo who deeply laments his purchase, as it has been attended with a very heavy loss, and it is not likely that he will obtain even a sixpence for the animal's punctured hide. It is expected that the wretched creature will not survive long, as he is in an exceedingly weak and tottering condition; and from castigations received in consequence of his former bad habits, there remain several *old sores*, from which issues a horridly fetid periodical discharge, of a dirty green colour." (An allusion apparently to the colour of the cover of the journal.) "Although scanty this discharge is so offensive, that the House of Longman and Co. has become notorious for its ill odour, and the only animals which now cheer the old hack by their presence are a few of the most ghastly and filthy of the Hospital Bats. Where the carrion is there will the crows be also."

After this elegant extract it will not be necessary to quote what was said of Johnstone, of Sir Anthony Carlisle, of Guthrie, Earle, Stanley, Sir William Bizard, or Sir Benjamin Brodie. All or nearly all had opprobrious nicknames, and in attacks upon the nepotism then rampant Sir Astley Cooper's nephews came in for many hard knocks. Bransby Cooper suffered most, and much more than he deserved. The libel action which he instituted was one of ten actions which were brought against the *Lancet* or its editor in the first ten years of its existence. Six of these were for libel, in which £8,000 in all was claimed and only £155 0s. 0½d. was awarded in damages.

In a few years the *Lancet* had sown its wild oats and settled down into its respectable and beneficent course, but in 1839 the *Medical Times* appeared and was nearly as abusive as the early *Lancets*. Much of its abuse was directed

against Wakley, to whom was allotted the part of Peachum in a parody of the *Beggar's Opera*, but these personalities did him no harm and he wisely disregarded them, except in one remarkable instance. His successful libel actions against the editor of this paper in later years had to do with other attacks upon him.

After the *Medical Times* had mended its manners and had become the reputable paper which it remained until its end in the eighties, the medical press ceased to have this particular kind of attraction for the student of manners and of the humours of medical life. Whether physicians and surgeons have become a less irritable genus or no, at least they do not show their annoyance in the unmistakable way which was usual a century ago, and the change is all for the better.

### THE HEALTH OF ABERDEEN.

WHAT must be, so far as we know, a new departure is the issue, not of an annual report, but of one covering a period of six years, by Professor Matthew Hay, as medical officer of health for Aberdeen. The six years are 1916 to 1921 inclusive, and the vital statistics have the advantage of being based on the census of 1921. The census population of 159,915 was less than had been assumed, and rates now calculated on it are correspondingly higher.

Housing in Aberdeen, in respect of the number of rooms in dwellings, is better than in the other three great towns of Scotland. Only 44 per 1,000 of its population live in one-roomed houses, as against 47 in Edinburgh, 89 in Dundee, and 128 in Glasgow. For two-roomed houses the corresponding figures are—Aberdeen 326, Edinburgh 329, Glasgow 498, and Dundee 508. Aberdeen is also better than the others in respect of the average number of persons per room in the smaller houses, Glasgow being the worst. In 1921 the birth rate in Aberdeen was 26.6 per 1,000, as against a mean of 21.5 in the five previous years. Illegitimate births were 9.2 per cent. of the total births in 1921—a lower figure than in any of the five preceding years. The death rate, 14.3 per 1,000, was also lower than the mean of the previous lustrum (15.1). The infant death rate per 1,000 births was 108, as against the previous five years' mean of 127, so that here there has been a very decided improvement, though, of course, the cool weather of 1921 made it a favourable year. Professor Hay's statistical tables contain many interesting figures; Table VI, for example, shows the survivors at the end of the first year of life as a proportion of the total population. In 1921 they were 23.7 per 1,000, against an average of 18.9 in the lustrum 1916-20. From 1861-70 to the end of 1921 the percentage fall in the death rate at different age periods has been as follows: 0 to 5 years, 45 per cent.; 5 to 15 years, 68 per cent.; 15 to 25 years, 63 per cent.; 25 to 45 years, 54 per cent.; 45 to 65 years, 28 per cent.; and 65 years upwards, 13 per cent. All periods of life therefore have shared in the improvement. In comparing the birth, death, and marriage rates of the great towns of Scotland, Professor Hay introduces a new feature by including Paisley, with 85,000 population, and Greenock, with 81,000, in the comparison. The additional figures are useful, though the rates do not differ in any very striking fashion from the others, excepting that malignant diseases seem less prevalent than in the larger towns, the difference between Paisley's rate of 10.4 and Dundee's 17.2 being notable. Illegitimate birth rates are also comparatively low in Paisley and Greenock.

The report contains a chronological survey of the six years.

Acute poliomyelitis prevailed in 1916, there being 79 cases. The type was mild, the fatality rate being 5 per cent. (case under one year old). In New York in the same year it was 24 per cent. The outbreak resembled epidemic meningitis in its distribution and transmission. The cases occurred in all parts of the city, and in houses above the average of cleanliness. In only a very few instances could any connexion be found between case and case. For the 75 cases that recovered with paralysis clinics were arranged. The cases were kept under observation for five years, and 51 completely recovered, whilst the remaining 21 are steadily improving. Typhoid fever became epidemic in 1918, when there were 97 cases due to milk infection from a country dairy farm. The originating case had been regarded as influenza, but the typhoid bacillus was found in the faeces and typhoid agglutinins in the blood. In 18 later cases were in contacts, and not due directly to milk.

situations has determined the presence of spinal compression. In a recent paper Cushing and Ayer<sup>2</sup> have shown the value of comparative pressure readings in five tumours of the cauda equina, in which the lumbar fluid taken from above the level of the tumour was highly albuminous, a finding which taken alone might have suggested that the tumour was at a higher level.

Still more valuable is Sicard's method of injecting lipiodol into the cisterna magna, and determining by x rays the level to which it spreads down in the subarachnoid space. This formed the subject of a demonstration by Mr. Percy Sargent at the Portsmouth meeting of the British Medical Association, at which he showed the possibility of establishing not only the site but also the extent of the tumour, by introducing lipiodol both by cisternal and by lumbar puncture. An account of his demonstration, illustrated by some excellent skiagrams, was published in a recent issue.<sup>3</sup>

The mechanism by which tumours reach and attack the cord was dealt with by Beriel of Lyons, who has recently published a series of articles on the subject.<sup>4</sup> In some cases neuro-fibromata appear to spread up the nerves from the periphery and to form either a large mass on a nerve root or a diffuse infiltration of the soft meninges; sometimes they actually invade the spinal cord. Being tumours of nerve substance they produce less damage to the function of the nerves or nerve roots than their size would suggest, and they often infiltrate the spinal root ganglia without giving rise to any root pains. In many cases the first symptoms attributable to them are those of compression of the spinal cord. Secondary carcinomata and sarcomata of the spinal bones, on the other hand, rarely pass through the dura mater, although they may produce a thickening on the inner surface of this membrane. Usually their effects are caused by pressure on the cord, and diminution of the blood supply to it. Occasionally spontaneous fracture-dislocation of the spine, due to its erosion by cancer or sarcoma, produces sudden and severe paraplegia.

The surgical treatment of spinal compression by laminectomy was dealt with by MM. de Martel and Robineau, and Beriel and Wertheimer. They all insisted that the operation should be done with the greatest care, and, in particular, that the cerebro-spinal fluid should be allowed to escape very slowly; rapid escape of the fluid or manipulation of the cord or of the roots caused rapid lowering of the blood pressure. Ether was the anaesthetic of choice. Finally, M. Bécère spoke of the treatment of spinal tumours by radiotherapy, and MM. Belot and Tournay recorded a case of spinal compression by tumour which appeared to have been completely cured by x rays, for the patient was able to walk as well as before. Many other cases of spinal tumour cured by surgical means were shown, and the meeting inspired the hope that, with the new and more exact methods of diagnosis and localization, the brilliant results which may follow the early eradication of spinal tumours will become increasingly common.

## THE BACTERIOLOGY OF PNEUMONIA.

IN a report on the bacteriology of pneumonia,<sup>1</sup> recently issued by the Medical Research Council, Professor Ernest Glynn and his colleagues point out that the returns of the Registrar-General show that while the fatality of many other infective diseases has greatly fallen during the past few decades, the number of deaths to be ascribed to pneumonia in one or other of its forms is still relatively high and shows little or no diminution. The present report is an attempt to shed a little fresh light upon the etiology and pathology of pneumonia by studying (1) 140 cases and 50 acute empyemata chiefly bacteriologically, but also clinically; (2) salivas from 25 normal persons bacterio-

logically; (3) 41 miscellaneous pneumococcal and streptococcal infections. The report also contains a considerable list of references to recent work on this subject.

In 90.7 of the cases of pneumonia examined by Professor Glynn and his colleagues the pneumococcus was found to be present. For isolating this organism from sputum or saliva mouse inoculation was superior to other methods. Lung puncture was found to be a safe and valuable aid to bacteriological diagnosis; 14 out of 31 cultures of lung juice obtained in this way were positive in case of adults, and 8 out of 13 in the case of children. The probability of finding pneumococci in the lung juice increased with their abundance in the sputum, or their presence in the blood. Pneumococci were successfully cultivated from the blood in about 45 per cent. of the cases of acute pneumococcal pneumonia examined from the third to the seventh day inclusive; it is significant that the mortality among the positive cases was 71.4 per cent. as compared with 8.3 per cent. in the negatives.

With regard to the differentiation of the pneumococcus from other organisms, stress is laid on the characteristic appearance of its colonies when viewed with a hand lens or under a low power of the microscope. As a rule the bile solubility test was of great differential value, but about 5 per cent. of the pneumococci were found to be either insoluble or but partially soluble in bile. The fermentation of inulin was of little diagnostic value, since only 18 per cent. of the Type I and Type II pneumococci examined gave a positive result, and about 14 per cent. of salivary streptococci were found to ferment inulin. When cultivated in the presence of blood, over 90 per cent. of the pneumococci produced methaemoglobin.

Of some 852 strains of pneumococcus-like organisms investigated, 2.7 per cent. were found to be intermediate between the pneumococcus and streptococcus. Pneumococcus strains conforming to one or other of the three defined types of that organism were usually more virulent to mice than other pneumococci. The Rockefeller agglutinating serums were of great value in identifying specimens of the various types of pneumococcus; direct typing from the peritoneal fluid of the mouse was successful in 68.8 per cent. of the cases, but in the rest the peritoneal fluid had to be subcultured before typing could be successfully performed.

A careful study was made of bacteria other than pneumococci present in the cases including streptococci, staphylococci, Gram-negative cocci, and *B. influenzae*. In ten cases streptococci were regarded as the probable causal agent. Haemolytic streptococci were only encountered in three cases; the others yielded non-haemolytic streptococci chiefly of the salivarius class which the authors consider to be of pathogenic significance in such cases, although usually such salivary streptococci are of no pathogenic importance. Only a single case of influenzal bronchopneumonia was met with; and in another the meningococcus was the probable cause.

A special feature of this report is the attempt which is made to correlate the clinical features of the cases with the bacteriological finding. It is suggested that the primary lobular pneumonia of children described by West is usually a Type I infection of exogenous origin; while his broncho- or catarrhal-pneumonia is usually either a Group IV infection of autogenous origin, or a streptococcal infection, as it often follows measles, whooping-cough, etc.

The few cases—six in all—in which the therapeutic value of Type I serum was investigated clinically gave an encouraging result, but most of those who have tried this treatment will agree with Professor Glynn and his colleagues that this serum is not likely to come into general use until it is sufficiently potent to be administered subcutaneously. Apart from the inconvenience of the intravenous route at present advocated, the large bulk of serum that it is necessary to inject is another very serious drawback to its general application. That serum of increased potency, or some other method of raising the patient's specific resistance, is urgently needed will be realized when it is stated that Professor Glynn estimates that during 1919 no less than 8,000 persons died in this country of pneumonia brought about by Type I pneumococcus—about twice the number that succumbed to diphtheria over the same period. The report gives full details of a vast amount of careful work, and is a valuable contribution to a subject of increasing importance.

<sup>1</sup> *Bacteriological and Clinical Observations on Pneumonia and Empyemata, with special reference to the Pneumococcus and to Serum Treatment.* By Ernest E. Glynn, M.A., M.D., F.R.C.P., and Lettice Digby, F.R.M.S., assisted by H. Wallace Jones, M.D. 1923. Medical Research Council Special Report Series No. 79.

were rendered to the public directly, in the extensive inquiries which were made into such subjects as the adulteration of food, nursing in workhouses, and the cholera epidemics on the Continent. In each of these and in others the *Lancet* stepped into the place which should have been occupied by a public authority, and the very valuable work which was done served still further to increase the respect in which the paper was held by the lay public. For even the most frenzied antivivisectionist or antivaccinator could not detect in these activities any possibility of the grinding of a medical axe.

The retrospect of one hundred years takes in a wonderful period in which the transformation in surgical practice was at least as startling as that made in other branches of knowledge and in industry. It includes the whole of the Victorian age, at which it is just now the fashion to sneer, but which to many of us seems in many respects the greatest in our history. Looking back now from the vantage point of a century, there does not seem so very much difference between the surgery of Astley Cooper and that of Ambrose Paré, yet the author of an historical retrospect in 1824 confidently stated that "Surgery, operative surgery, has now nearly achieved all that can be expected from it." So many advances have been made in our time that we expect more of the future than did the writer in the *London Medical and Physical Journal*, and putting all that anaesthesia, antiseptic and aseptic surgery, and radiology have done on the credit side, we are not so confident of finality now as our forefathers were in the days when the great Sir Astley performed minor operations in his consulting room with the assistance of his footman, did not invariably remember to wash his hands between operations, and received the Prince Regent with blood-stained shirt-collar and cuffs. Imagination boggles at the attempt to realize what a prolonged major operation, such as a difficult lithotomy, then meant to the unfortunate patient of any class in society, and it is fortunate for us if we cannot conceive what were the sufferings of a patient submitted to operation in a public hospital, before death put an end to them, as it so often did.

The fortunes of innovations and improvements in surgery and medicine may be followed week by week in the pages of the *Lancet*, some quickly and widely accepted and some stubbornly opposed by the many and only advocated by the enlightened few, until the logic of facts carried conviction to all. We may also see some inventions, such as phrenology, extolled by many besides the editor of the *Lancet*, only to fade into insignificance as time proved their worthlessness.

Our contemporary has been fortunate in having as its editors the three generations of the family of Wakley, and the present occupant of the editorial chair, Sir Squire Sprigge, to whose practised pen we think that we may venture to attribute this masterly summary of the activities of a century which ought to find a place on the bookshelves of every medical practitioner. There is no other man living so well qualified for this task as the author of the *Life and Times of Thomas Wakley*, who has himself been a member of the staff of the paper for over thirty years and for fifteen years its editor. Fortunate it has also been in the groups of distinguished assistants whom its editors have from time to time chosen to assist and advise them. Their names are recorded in the supplement, and a consideration of them shows that with their support the *Lancet* must have deserved the success to which it attained.

## THE USE AND ABUSE OF OBSTETRIC FORCEPS.

THE Annual Meeting of the British Medical Association in Portsmouth was the occasion of many interesting and important discussions, but perhaps calculated to interest a wider section of the profession than that on the use and abuse of obstetric forceps, which was introduced by Mr. Comyns Berkeley, Dr. J. S. Fairbairn, both well known to the profession in midwifery and gynaecology. In dealing with the "abusive" side of his subject Mr. Comyns Berkeley dealt as faithfully with his colleagues in the schools of this country as with the practitioners of other countries, neither the one section of the profession nor the other entirely resent his criticism, although they can justifiably resent his criticism, although they do not all entirely agree with his views. We find this particularly, because a querulous note did not find its way into the discussion, and some general practitioners in his audience seemed to resent what they deemed a slighting judgment. A calm perusal of what Mr. Comyns Berkeley said will, we are confident, extinguish any such feeling wherever it may have been generated, and ourselves we welcome the opportunity provided by the publication of his paper to record our cordial appreciation of his public spirit in calling attention to what we believe to be bad in the teaching and in the practice of present-day midwifery. It is quite true that this is no less than the duty of the specialist in his subject—a duty owed alike to the public, to his colleagues in the profession, and to his own conscience. But at the same time it always takes courage to make such an indictment in public; and in the present instance this is particularly the case, because the general practitioner is more sensitive of criticism than his midwife. A shrewd element of truth lurks in the epigrammatic statement of an eminent obstetrician, now regarded as a specialist in midwifery. "It is merely one way of stating the obvious fact that in midwifery the general practitioner does, and is expected by the general public to tackle single-handed emergencies and difficult operative deliveries, the equivalent of which in general surgery or in medicine would appear both to him and to his patients to call unequivocally for the specialist's services in private or in hospital."

Such is the prevalence of the use of forceps in midwifery to-day, and so wide is the range of conditions in which, justifiably or unjustifiably, may be claimed as indications for the operation, that a discussion on the subject is bound to be discursive and to range over almost the whole subject of practical midwifery. The root causes of the abuse of forceps are to a large extent the same as the causes of bad midwifery in general, and of the persistent puerperal mortality from which we suffer. They are to be traced not only to the imperfections of teaching, the lack of ante-natal care, and the lack of skill or judgement on the part of an individual practitioner; they are entangled with the economic aspect of midwifery amongst the industrial and poorer sections of the populace, and with the ignorance on the part of the public as to the conditions necessary for the safe delivery of a woman. We are rather surprised that more emphasis has not been laid upon the economic aspect of the case. For no part of his work is the practitioner less adequately paid than for his midwifery, and it is surely no reflection upon the profession to suggest that if more appropriate fees were forthcoming more time and attention would be

The Royal Medical Benevolent Fund (11, Chandos Street, London, W.1) has received from Sir Thomas Barlow a donation of £300, which has been invested for the benefit of the annuitants.

Sir Robert Jones, who is chairman of the Central Committee for the Care of Cripples, addressed a large meeting of voluntary workers among the 9,000 cripples on the registers of the Shaftesbury Society and Ragged School Union at the John Kirk House, John Street, Tottenham, London, on September 28th, with Dr. T. M. Kelynak in the chair. Sir Robert Jones emphasized the need of a national scheme for dealing with the hundred thousand juvenile cripples in this country, and illustrated from the organization already in being in Shropshire and Oxfordshire the kind of provision that is possible on a national scale.

The Lancashire Insurance Committee recently discussed a proposal to assist Mr. Spaldinger of Geneva to proceed with his production of serums and vaccines for the treatment of tuberculosis. It was resolved that in May last a deputation from the Committee visited the Ministry of Health to secure approval for a grant of £1,000 to be made for this purpose out of the local General Purposes Fund. Dr. H. P. Oldham of Morecambe challenged a statement that the medical profession accepted the Spaldinger treatment as effective. The proposal that a subcommittee should go to Switzerland to investigate the financial position was defeated by 15 votes to 10, and a motion that the whole matter be referred back was carried.

The Right Hon. Sir William Johnson-Hicks, Bt., M.P., Minister of Health, has appointed the Lord Krishna, M.P., to be his parliamentary private secretary, Mr. Douglas Veale, of the Ministry of Health, to be his private secretary, and Mr. H. Nevil Barker, of the Ministry of Health, to be his assistant private secretary.

The annual dinner of the Chelsea Clinical Society will be held at the Cafe Royal, Regent Street, on Tuesday, October 30th, at 7.15 p.m. The honorary secretary is Dr. P. Seymour Price, 41, Sloane Gardens, S.W.1.

The Chalmers gold medal for the best work on tropical medicine by investigators under the age of 45 has been awarded to Dr. K. Huband, general secretary of the Societe de Pathologie exotique of Paris.

Professor Benoit of Bordeaux and Dr. C. McIntyre, sub-director of the Paris Institut Pasteur, have been nominated Grand Officers of the Legion of Honour.

Dr. B. S. Science, who invented the well known test for diptheria susceptibility, has been made an extraordinary professor of pediatrics in the University of Vienna.

At the meeting of the French Association of Urology in Paris on October 10th, when Professor Andrieu of Nancy presided, the chief subject for discussion was the treatment of gonorrhoea by serotherapy and vaccination.

The Berlin Medical Society has closed its library owing to financial stress.

The Chartered Society of Massage and Medical Gymnastics is holding its annual congress on October 5th, 6th, and 7th, in the morning, when Professor G. Elliot Smith delivered a lecture on "Muscles and nerves." In the afternoon Dr. Bellis Clayton gave a demonstration at King's College Hospital, and in the evening Mr. A. S. Blundell Barnett gave a lecture on the Whigmore Hall on "The knee-joint."

On Saturday Sir Alfred Ebbitt will give a lecture at 3 p.m. on Saturday at the Northampton Polytechnic Institute at 5 p.m. Dr. R. Frier, and Miss Driver will give a demonstration of the Whigmore Hall by Dr. G. H. Hunt and Professor R. P. Frier, and Mrs. P. Frier.

The chief subjects for discussion at the meeting in Paris on October 12th of the French Society of Orthopaedics will be the carpus, opened by Dr. Laroche of Lyons; cysts of bone (omitting hydatid cysts), opened by Dr. Roeder of Paris; and congenital elevation of the scapula, opened by Dr. Delebet of Brussels.

The Journal of the American Medical Association states that approximately 10.6 per cent. of the graduating classes of 1920 and 1921 at the United States Naval Academy failed to attain the minimum height for officers of 5 ft. 6 in., and an attempt was made to stimulate growth in a group of under-sized midshipmen, who volunteered for the experiment, by enucleating the thyroid. The conclusions arrived at by Captain D. N. Carpenter and Lieutenant D. Ferguson, of the United States Navy, were as follows: growth is not stimulated by thyroid and pituitary therapy in persons at or near maturity; preparations of anterior pituitary extract appeared to be inert as growth stimulants in these men, when administered orally; there is possibly an appreciable percentage of thyroiditis in the United States.

Lieutenant-colonel in 1917, was transferred temporarily to the non-effective list, on account of ill health, in September, 1920, and retired in July, 1921. Soon after joining he served in the China expedition of 1920, and took part in the relief of Peking, receiving the medal with clasp. He then joined the political department, and was successively held the posts of Resident Surgeon in the Persian Gulf, at Basra, and as Agency Surgeon of Debel, and subsequently of Kach and Ushay, in Rajshahi. At the beginning of the recent war he rejoined for military duty, serving from November, 1914, to March, 1916, as medical officer of the 106th Hazara Pioneers, when he took part in the operations in Baluchistan in June and July, 1915. From March to May, 1916, he served in the Indian Expeditionary Force in Mesopotamia, and from the middle of 1916 in the operations in Persia, as senior medical officer of the Shiraz Column.

Surgeon Captain Edward Dominic Joseph O'Malley, R.N. (retired), of Southsea, died suddenly at Haslar Hospital on September 20th, aged 55. He was the son of the late Deputy Inspector-General O'Malley, R.N., who died at a Middlesex Hospital, taking the M.R.C.S. and L.R.C.P. Lond., in 1855. Entering the navy as surgeon in 1857 he attained the rank of surgeon commander on May 25th, 1911, and retired with the honorary rank of surgeon captain on August 15th, 1922. He leaves a widow but no children.

## Medical News.

A discussion on the use of insulin in general practice will be held by the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on Tuesday, October 9th, at 4.30 p.m. The subject will be introduced by Professor H. Macleod, Dr. George Graham, and Professor J. J. R. Macleod of Toronto.

The annual general meeting of the West Kent Medical-Chirurgical Society will be held on Friday, October 12th, at 8.45 p.m., at the Miller Hospital, Greenwich, S.E.10. Clinical cases will be shown by Mr. William Evans, Mr. C. A. Joll, Dr. H. Nockolds, D.S.O., and Dr. H. Pritchard.

In order to further the study and teaching of dermatology in London a comprehensive scheme of co-operation has been completed in connexion with St. John's Hospital for Diseases of the Skin. The teaching will be carried out at St. John's Hospital in Leicester Square, under the auspices of the London School of Dermatology; it will be conducted by the honorary medical staff of the hospital, together with the physicians in charge of the dermatological departments of the twelve London hospitals with undergraduate schools attached. Full details will be published later, but in the meantime attention may be drawn to the announcement which appears in our advertisement columns of lectures to be given on Tuesdays and Thursdays at 5 p.m. during the winter session.

The sixth congress of the Spanish Association of Urology will be held in Madrid, under the presidency of Dr. Barragan, from October 17th to 20th. The subjects to be discussed are: Hypogastric cystoscopy, introduced by Dr. Camilla of Bilbao, and indicated for operation in reno-ureteral lithiasis, introduced by Dr. Miravet of Madrid.

The thirty-second French Congress of Surgery will be held in Paris from October 8th to 13th, with Dr. Demom as president. Drs. Jeanbent and Raebach will open a discussion on blood transfusion. Drs. Begonin and Savatier on the surgical treatment of genital prolapse, and Drs. P. Mathieu and Villaret on non-calculous obstructions of the chief biliary passages. Further information may be obtained from the secretary of the congress, 12, Rue de Seine, Paris (VI).

The annual health week of the Deptford Borough Council is being held this week in the Borough Hall, New Cross, concluding on Friday, October 5th. The programme includes lectures, infant consultations, and two films dealing with public health subjects; there are also numerous stalls exhibiting infant foods, model meals, model garments, and so forth.

The fourteenth congress of the Italian Society of Ophthalmology, Polioptico, Rome.

The legislators of the States of Washington and Oregon recently passed laws prohibiting the manufacture and sale of margarine containing vegetable oils, but trading interests in both States have succeeded in getting the laws suspended until November, 1924, when they will be submitted to a referendum.

The thirty-second French Congress of Surgery will be held in Paris from October 8th to 13th, with Dr. Demom as president. Drs. parts of the country and all classes of the community. Nothing is more obviously a weakness of the present situation than that practitioners should be expected, and should indeed be compelled, to do obstetric operations in circumstances and surroundings that would paralyse the activity of a general surgeon. Thirdly, there is the importance of greater reliance on what Dr. Fairbairn called the "first line of defence"—the natural efforts—and the observance of "the test of labour" in all primigravidae. Fourthly, we would specify in particular that the forceps should never in any circumstances be applied until the cervix is fully dilated. We believe that if this one rule were observed strictly Mr. Berkeley's ground for complaint would be diminished almost to vanishing point. Never is brute force to be used. If it prove really necessary the case is not properly one for forceps delivery. Gone are the days when an obstetrician could afford to boast of the very small pelvis through which he had dragged a moribund infant. To be faced with the alternative of extracting such a child by brute force through a pelvis which is bound to be seriously bruised and lacerated or of performing craniotomy on the living child is often the fate of a practitioner in the country, or in urban districts where hospital facilities for the performance of Caesarean section are lacking. It sounds almost too idealistic to say that the time is surely coming when such a cruel dilemma will cease to present itself. But it is the case—provided we all religiously practise ante-natal examination and care, and preach the value of it to our patients and to the public, in season and out of season.

### THE SCHOOL OF HYGIENE.

We have more than once commented upon the lengthy incubation period, now amounting to six months, which has followed the decision to proceed to the appointment of a director of the new School of Hygiene. Our contemporary, the *Medical Officer*, in its issue of September 15th, expresses an astonishment, which we share, at the delay. Other opinions expressed by our contemporary are, we think, less well grounded. Its opinion that the director should be "a practical man with a knowledge of research, with a broad outlook on hygiene, with imagination, tact, discretion, and a wide experience of men and affairs," will certainly be endorsed by all; but the inference that "the best and most up-to-date sanitarian of the English public health service is the only possible appointment which can be made to ensure the success of the school and command the confidence and support of public health officers in this country and abroad" does not follow, and even suggests some confusion of ideas.

The object of the School of Hygiene is certainly not to provide instruction in the technique of public health administration, any more than the object of a university school of jurisprudence is to teach the practice of the courts. Many years ago, in a criticism of English legal education, Walter Bagehot said that "the training for judicial legislation should be one of jurisprudence in the highest sense—of the jurisprudence which Burke must have been thinking of when he called it the 'pride of the human intellect.' It must be a knowledge of the reasons which make laws good or bad, eligible or ineligible in given cases. But no one will contend that such knowledge is now taught 'in chambers,' nor is it possible that it should ever be taught there." Bagehot argued that the qualities which enable a lawyer to succeed in practice might

be wholly alien to those requisite in the good teacher, and we think he would have been surprised to hear that a successful barrister or even a popular judge would, on that account, be a suitable source of inspiration for a school of jurisprudence.

These considerations are fully applicable to the case of the School of Hygiene. That its director should have something more than the general knowledge of research possessed by medical officers of health in common with other educated men, that he should have acquired the more intimate knowledge only to be gained by direct participation in some form of research and necessarily rarely possessed by men actively engaged in public health administration, are paramount qualifications. If there is any English medical officer of health who possesses these qualifications and is willing to undertake the duties of directorship, his claims to consideration are very great. But we deprecate strongly any emphasis of the "practical" aspects of the matter. A school of hygiene which professed to manufacture sanitary administrators would be as great a laughing-stock as a school of jurisprudence which attempted to manufacture legal practitioners. It is the business of a university to teach principles. Those who have been well grounded in principles will profit by the practice of the world of everyday life, and become sound practitioners.

The ideal director of a university school is a man of principles in that sense. That he happened to be by training a bacteriologist, a chemist, or indeed a research worker in any department of human knowledge whatsoever, should not operate as a disqualification. It is the personality of the man himself, his breadth of mind and ideals, which are all-important. That these high qualities are to be found in the ranks of the English public health service we are proud to think is certain, but we are equally confident that they are to be found in all the other branches of the medical profession.

### FREE DISTRIBUTION OF INSULIN IN ONTARIO.

THE Provincial Board of Health of the Province of Ontario has issued a pamphlet<sup>1</sup> giving information regarding the free distribution of insulin in suitable cases of diabetes, arrangements having been made by the Board to supply insulin free to medical practitioners for patients in Ontario who are unable to pay for the drug themselves. It is emphasized in the pamphlet that the majority of patients suffering from diabetes do not require insulin, and can be better treated by dietetic measures alone, and, in order to determine the necessity for insulin, patients are whenever possible placed in a hospital for three weeks to determine the severity of the disease. In hospital it is advised that the following investigations should be carried out: estimation of the quantity of urine passed in twenty-four hours; examination of urine and quantitative determination of sugar in urine; blood sugar determination. The patient should then be placed on a weighed maintenance diet calculated from the patient's basal metabolic rate, and examinations should be repeated daily to determine the power of carbohydrate utilization. Then, if insulin is required, the amount and the time of the dose should be scientifically worked out. While in hospital the patient should be taught how to weigh and prepare his diet; how to examine his urine; the symptoms and danger signals of his disease; how to administer insulin to himself; and the symptoms and treatment of overdose of

253. **The Treatment of Malaria with Lumninal.**  
J. STRASSBURGER (Klinisches Wochenschrift, August 20th, 1923, p. 1592) gives his experience of the treatment of malaria with lumninal. He reports in detail nine cases of malaria in this drug in the last two years. He concludes, from his experience, that continued treatment of malaria with lumninal in a daily dose of 0.1 gram or a little less diminishes markedly the number and severity of the attacks. Improved general condition and increased activity are also observed after discontinuing the drug, in contrast to the attacks of malaria which occur. Bad results were not observed when the dose mentioned was taken daily. An increase of the dose was not necessary. The drug was given in the evening in a dose of 0.1 gram, or half this quantity was given twice a day. During the lumninal treatment many patients complained of a tendency to constipation, so that aperients had to be given from time to time. The action of lumninal appears in milder form, as in epilepsy, to be specific. Other observations have also recommended it.

524.  
**Chronic Acquired Trophodema.**  
 A. HENRY (*Paris med.*, July 14th, 1923, p. 49) states that since 1893, when Henry Meigs read his paper before the ninth congress of neurologists and alienists at Angers, all the dys trophic cedemas of unknown cause, and probably of nervous origin, have been grouped together under the name of "trophodema." In some cases it is an isolated occurrence, in others it is hereditary and familial. Sometimes it is congenital. Acquired trophodema, of which Henry records a case, may be a sequel of various infectious diseases, traumatic, nervous disorders, or without any definite cause. The lower limbs are chiefly affected, as a rule on one side only. The upper limbs and face are rarely involved. It is easy to distinguish chronic cedema from acute cardiorrenal cedema, phlebitis, cachectic cedema, or oedema due to tabs, syphilis, gonorrhea, hemiplegia, or exophthalmic goitre. The pathogenesis is obscure. The condition has been attributed to disturbance of the sympathetic system or to a neurotic disorder. Treatment consists in administration of a nerve tonic such as strychnine, arsenic, or sodium glycerophosphate, or partial amputation of the affected limb.

cases was in a woman, aged 22, in whom trophodema of the right lower limb developed at the age of 20, following an attack of erysipelas at 11. He attributes the condition to changes in the cells of the cord in the lumbosacral region, due to the acute infection.

257. Prophylaxis of Measles by Serotherapy.

G. SALOMON (*Berl. med. Woch.*, August 31st, 1923, p. 1151) notes that according to official returns the mortality from measles in Germany in the first quarter of 1923 was 4.7 times as great as in the previous year. In a children's asyrum in Berlin he has been confronted by the problem of preventing measles from spreading to young and ailing children. He was unable to obtain an adequate supply of the serum of convalescents, and he was therefore obliged in many cases to fall back on the serum of adults who had contracted measles in childhood. The following observations suggest that this serum is almost as valuable in averting an attack of measles as is the serum taken from a child in the stage of convalescence. At the asyrum there were 199 infants over the age of 3 months. Infants under this age were not included in this investigation because they are comparatively immune to measles. The 193 infants were classed in three groups: The first included 60 infants who were given no prophylactic treatment; the second group included 62 infants given prophylactic injections of the serum of convalescents; the third group included 76 infants who were given prophylactic injections of the serum of adults. All three groups were exposed to infection, and every one of the

251. An Epidemic of Extra-genital Syphilis.  
 Dr. GERTZ (*Deut. med. Woch.*, June 15th, 1923, p. 782) gives an account of an epidemic of extra-genital syphilis in a mountainous district in Holsstein. A young girl, the first case, was examined by Dr. Gertze, who was subsequently notified by the "Land" authorities. None of the other labourers possessed venereal disease. The labourers ate and drank from the same vessels, and one ate the other's bread and drank from the other's glass. The epidemic was confined to the labourers and their families, and other signs of old syphilis were not observed. The epidemic was confined to the labourers and their families, and other signs of old syphilis were not observed. The epidemic was confined to the labourers and their families, and other signs of old syphilis were not observed.

252. **Rickets and Tetany.** H. B. Mills (*New York Med. Journ. and Med. Record*, August 15th, 1923, p. 193) urges the importance of distinguishing between the two kinds of rickets arising from the disproportion between the amount of calcium or phosphorus in the system, in one (low calcium rickets) the calcium being low and the phosphorus normal or above, while in the other (low phosphorus rickets) the phosphorus is low and the calcium normal or above. The estimation of the blood risk of a day or two's delay in waiting for the laboratory report, a little over 10 mg. of calcium and 5 mg. of phosphorus to 100 c.c. of serum being normal. While the administration of both calcium and phosphorus in all cases of rickets may be of use, the advantages of being able to give the maximum dose of one of the one that is deficient, and the one that is normal or above, as ascertained by a laboratory test, is obvious. Heredity may occasionally be a predisposing causative factor, but in this connection more weight attaches to prematurity. Tetany, which may occur apart from rickets, as when parathyroid insufficiency interferes with the calcium metabolism, is due to low calcium content, and is therefore essentially a complication of low calcium, and is therefore essentially a complication of low breast- and bottle-fed infants, so that diet alone is in both breast- and bottle-fed infants.

College of Surgeons of England) were all sound; he exhibited besides many specimens of the soil, the vegetation, and the mineral water, with analyses. Porto Santo is now accessible by fairly large steamers, but Dr. Grabham, who is now well advanced in his eighty-fourth year, accomplished the voyage of forty miles from Madeira in an open sailing boat during the night in safety and with satisfaction.

#### EARLY MEDICAL JOURNALS.

EVERYONE interested in the history of medical journalism who can read Italian will enjoy the scholarly article on the dawn of Italian medical journalism by Professor Castiglioni,<sup>1</sup> the well known medical historian of Trieste, to whose fascinating study of Benvenuto Cellini we have drawn attention (March 10th, p. 433). Although primarily concerned with the history of early Italian medical journals, the article contains several instructive facts relating to the origin, not only of medical and scientific journals, but also of the lay press. The first newspaper, as we pointed out in "Nova et Vetera" on October 28th, 1922, page 808, was due to the initiative of a medical graduate of Montpellier named Théophrastus Renaudot, who published the first number of his *Gazette* on May 30th, 1631. The first scientific journal in which medical articles appeared would seem to have been the *Journal des Sçavans*, which was published in 1665, a few months before the *Philosophical Transactions*, the organ of the Royal Society of London, first appeared. The earliest journals devoted exclusively to medicine had only a short existence. In 1679 the empiric Nicolas de Blegny started the *Journal des nouvelles découvertes sur toutes les parties de la médecine*. It continued publication for only three years, when the editor, as the result of accusations of ignorance and immorality brought against him by the Paris Faculty of Medicine, was thrown into prison. The first medical journal to be published in England, *Medicina Curiosa*, appeared in 1684, but it had an even briefer span of life; Germany's first medical journal, entitled *Der patriotische Medikus*, survived from 1724 to 1726. The first Italian medical journal, *Giornale di medicina*, was published at Venice in 1726. It was issued weekly, and consisted of eight quarto pages; it was in two parts, the first containing reviews of the principal foreign journals, and the second articles by Italian medical writers. It ceased publication in 1781, and two years later another appeared entitled *Giornale per service alla storia ragionata della medicina di questo secolo*, which lasted until 1795. Dr. Castiglioni devotes a special section of his article to the account of a journal which was published monthly at Trieste by Benedetto Frizo, a well known physician and writer, under the name of *Giornale medico e letterario di Trieste*. Its interest, however, lay less in its medical importance than in the fact that it represented an independent expression of Italian thought in spite of Austrian repression. With the beginning of the nineteenth century Italian medical journals began to assume a greater importance and enjoy a wider circulation than before. The *Giornale della Società Medica-Chirurgica di Parma*, which first appeared in 1806 and lasted till 1815, occupied a very important position in Italian medical literature. It was published monthly and consisted almost entirely of signed original articles. Dr. Castiglioni gives the following statistics relating to medical journals in recent years: At the end of 1913 the total number in existence throughout the world was 1,654, of which 630 were American, 461 German or Austrian, 268 French, 152 British, 75 Italian, and 29 Spanish. Dr. H. O. Hall, director of the Surgeon-General's Library at Washington, calculated that the

number fell from 1,895 in 1916 to 1,240 in 1921, so that the war was responsible for a reduction in the number of medical journals by about a third.

#### BIOMATHEMATICS.

WE think it was no less a man than Sir Francis Galton who, having occasion long after his school days to study some properties of an ellipse, was a little disheartened by the mass of information presented in a textbook of conic sections. Certainly smaller men, intrigued by the mathematical notation of so many physiological, biochemical, and medico-statistical papers, who have consulted the school books of their sons, have experienced even more disappointment than Galton, who had a first-rate mathematical brain. Many attempts have been made to explain to grown men the notation of mathematical methods, but we are not acquainted with any work which covers so wide a field as Dr. W. M. Feldman's *Biomathematics*.<sup>1</sup> Dr. Feldman does not attempt to teach mathematics *sensu stricto*, and he refrains from the logically rigorous demonstration of various fundamental theorems. What he does is to explain the notation and to illustrate each symbolic process upon a concrete example likely to interest a medical reader. Many of the examples are themselves of considerable biomedical interest; hardly any—except perhaps those of animal mechanics—are so much simplified as to remind one of the immortal very small elephant whose weight might be neglected. The concluding chapter, on biometrics, is based upon Caradog Jones's textbook, and some sections of it are rather beyond the scope of readers not specially interested in mathematical statistics. In his luminous introduction Sir William Bayliss uses the following words: "The variety of knowledge that the physiologist, for example, has to call to his aid is so vast that he really cannot spare the time to master these textbooks [that is, regular textbooks of mathematics]. The present work seems to me to have succeeded in giving just what is likely to be useful." The book is not, of course, easy reading; the inherent difficulties of the subject are considerable, but Dr. Feldman has taken great pains to reduce difficulties to a minimum. The preparation of such a book as this must have been difficult and laborious. We hope that the medical profession will profit by the author's labour. He has really left no excuse for the neglect of scientific papers employing mathematical notation by those educated men who sometimes almost seem to boast that they cannot understand "mathematics."

#### ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

THE St. Andrews Institute for Clinical Research, founded by Sir James Mackenzie five years ago, has in that period accomplished a great deal of valuable research work in clinical medicine, much of which has been reported by Sir James Mackenzie and his fellow workers in our columns. The latest instance is the essay by Professor Herring on the regulating and reflex process, the first part of which is published in our issue of this week. The Institute occupies two large houses looking out on the North Sea on the further or eastern side of the famous golf links. As he has himself recounted in this JOURNAL, Sir James Mackenzie has succeeded in enlisting the active co-operation not only of most of the scientific staff of the University of St. Andrews, but also of many medical practitioners in the town and district. Patients are seen at the institute, researches are carried out, and elaborate notes kept. Visiting practitioners are welcomed, and Sir James Mackenzie gives frequent informal talks about what has been found out, and

<sup>1</sup> *Biomathematics. Being the Principles of Mathematics for Students of Biological Science.* By W. M. Feldman, M.D., F.R.S.E. Introduction by Sir W. M. Bayliss, M.A., D.Sc., LL.D., F.R.S. London: C. Griffin and Co., Ltd. 1923. (21s. net.)

[illegible]

Let me warn you that you will not see in private practice the same sort of cases which you meet with in hospital. In a great hospital you have gathered together persons afflicted with severe and pronounced disease and cases which, from their nature and environment, are beyond the possibility of proper treatment by the outside practitioner. In industrial districts and mining areas such cases are more frequent, but if your lot should be to look after the well fed, well clothed, well housed sections of the community you will be surprised at the small proportion of cases of really serious illness you will be called on to attend. Being familiar with all the grave manifestations of disease which you meet with in the wards, you will be able to go with exceeding confidence into a house, in the sure and certain faith that whatever you may there find cannot be worse than that which you have habitually seen treated here. But above all things, never forget to carry with you into your private practice that habit—the most important of any you may acquire in hospital—the habit of always examining and noting the condition of every organ in every case. A very large proportion of the mistakes made are due not to any lack of knowledge or skill but solely to the fact that one or more important organs have not been carefully passed under review.

Cultivate at all costs that which, wanting a better term, I will call your clinical instinct. Make your diagnosis with your brains, your eyes, your fingers, and your ears; and then bring in your machinery to confirm or disprove your findings. Of late years I have noticed that many men are chary of expressing an opinion, even upon a fairly obvious case, until they have made the way plain before them by laboratory tests and instrumental assistance. To use the invaluable methods of modern research in this fashion is to degrade them to the function of crutches, whose constant use will enfeeble your intellectual muscles and doom your independent perceptions to atrophy. Times without number you will find the eye, the finger, and the stethoscope, used with a trained clinical intelligence, beat the test tube, the  $x$  ray, and the swab.

At all times be very gentle with your patients. The heaviest-handed and kindest-hearted physician that ever went round the wards of this hospital, what time he severely pounded an extremely tender and sensitive abdomen thus exhorted the students standing round: "Never excruciate your patient; you can find out all you want without excruciating your patient; never excruciate your patient." The particular victim in this case had the gift of humour and fully appreciated the precept and the example. Take great pains to make an invalid as contented as possible; let the yoke of your restrictions be as easy and the burden of your directions as light as the exigencies of the case will allow. The bed of sickness is not the bed of Procrustes; you must fit the bed to your patient, not your patient to the bed. The drastic drugs which are the salvation of a navy are anathema to a thin-skinned, fair-haired, blue-eyed girl. Never prescribe for a person until you have shaken hands with him and thus assured yourself of the texture of his skin; and in speaking of treatment let me remind you that year by year you will see the rise and follow the decline and fall of many loudly vaunted remedies. It will be your lot to watch an endless procession of fetishes, each one surviving until pushed out of the limelight by its successor. In the morning they flourish like a green bay tree; in the evening they are cut down, dried up, and withered.

"Truditor dies die,  
Novaeque pergunt interire lunae."

In the course of your future work you are bound to come in contact with your fellow practitioners in many ways and on many occasions. In our profession we are extremely individualistic, and friction at times is inevitable. If you make it a rule to put yourself in the other man's place, and act as you think he should act towards you, fighting will be at a discount and ethical rules superfluous. Should you ever hear from a lay person that a doctor has given some extraordinary opinion, don't believe it. A dear old friend of mine once asked me whether it was possible that a certain person had some fearful and wonderful disease. I replied, "No." "But her doctor

told her so," she said. I told her that no doctor could have told her such a medically and surgically ludicrous thing. "But," she insisted, "So-and-so distinctly told me that was what her doctor said." My reply finished the discussion—"I am quite sure he did not, for I am So-and-so's doctor."

In whichever branch of your profession you finally practise you will make lifelong friendships. You will acquire merit where you deserve blame, and blame when worthy of praise. For those of us whose lot, sooner far than later, will issue from the Urn—whose laurel, like the arms and war-weary lute of Horace, will soon be laid aside—the time is at hand when we must humbly hope that we may say, with him, "Militavi non sine gloria."

### ST. MARY'S HOSPITAL.

THE commencement of the winter session at St. Mary's Hospital Medical School, on October 1st, was signalized by the holding of the annual dinner of past and present students that evening at the Connaught Rooms. The chairman, Mr. V. Warren Low, C.B., senior surgeon at the hospital, was supported among many others by Mr. H. J. Waring, Vice-Chancellor of the University of London; Mr. A. R. Prideaux, Chairman of the Hospital Board; Surgeon Rear-Admiral J. Chambers, the new Medical Director-General of the Royal Navy; Lieutenant-General Sir William Leishman, F.R.S., Director-General A.M.S.; Air Commodore David Munro, Medical Administrator R.A.F.; Sir Leonard Rogers, Sir John Broadbent, Sir William Willcox, Mr. Ernest Lane, and the Mayor of Paddington. The chairman, in proposing prosperity to St. Mary's Hospital and Medical School, began his entertaining speech with a few personal reminiscences drawn from nearly forty years' association with the Hospital and its School. He remarked on the praiseworthy shortness of the toast list, observing that after-dinner speeches were often too much like sermons, and modern sermons too much like after-dinner speeches. St. Mary's, he said, could not claim antiquity; it had only reached the respectable age of 80 years, and must rather look more to descendants than ancestors for its traditions. Nevertheless, the Hospital had already been most fortunate in the distinguished line of physicians and surgeons who had devoted themselves to its service. Among those Mr. Warren Low mentioned in particular the Lane family, Dr. Cheadle, Sir William Broadbent, and Mr. Edmund Owen. The toast was responded to by the Chairman of the Hospital Board and the Dean of the Medical School. Mr. Prideaux in his reply was able to give a satisfactory account of the hospital's finances during 1922 and 1923; instead of heavy deficits as in the two previous years, the income now balanced the expenditure. None of the hospital wards were closed, but the problem of providing paying wards for persons of moderate means still awaited solution. Dr. C. M. Wilson, in his brief account of the valuable fortunes of the Medical School, spoke first of the valuable work carried out in the teaching of the preliminary subjects. The success of the school, he said, must be based on its anatomical and physiological departments. The unit system was a great feature of the present-day clinical teaching, though this had meant the sacrifice of beds by other members of the medical staff. The students now numbered 400, but the difficulty of providing material for the instruction of so many had been largely met by the arrangements entered into by St. Mary's with the Paddington Infirmary, and more recently with Queen Charlotte's Hospital. The post-graduate course during the past summer had been most successful, and was attended by very large numbers, showing the appreciation felt for this work by old students. In response to the chairman's invitation, Dr. Milner Moore of Eastbourne, as the senior of the old students present and one of the founders of the annual dinner, told very briefly something of the origin of these annual gatherings in the late sixties. The concluding toast was the chairman's health, submitted in very warm terms by his friend and colleague on the Council of the Royal College of Surgeons, Mr. Waring.

the dental school for studying medicine and surgery; it was hoped that they would go on to take the degree of practitioner of dental surgery of the University of London and that the majority of them would obtain a medical as well as a dental diploma.

Mr. H. J. Waring, having presented the scholarships, prizes, and certificates, addressed the students. He said that it had occurred to him that it might be useful to the students if he offered some remarks on the way in which they should arrive at their conclusions in the practice of medicine, and how it could best be ensured that those conclusions were the correct ones. If the conclusions were to be sound they must be based on accurate data. He laid stress first upon the intelligent use of the senses. The stethoscope revealed nothing except to the trained and discerning ear, and the finger of the physician or surgeon was itself an instrument so delicate and sensitive that he could not overestimate its services. On more than one occasion he had seen a medical student make a careful examination of an artificial eye and make a report on its optical capacity without discovering that it was not real. Why was Lister such a great force in surgery, and what was it that enabled him to revolutionize surgical practice throughout the world? It was his constant habit of patient observation. There was nothing he more emphasized in his teaching than the value of the observant eye. He was also very keen on the necessity for a thorough grounding in the preliminary sciences.

The general practitioner was concerned less with the prosecution of research than with immediate diagnosis and treatment, but this offered as great a sphere as any other for continuous and intelligent observation. The general practitioner had on occasion to make quick and important decisions under conditions of extreme difficulty, and the use of eye, ear, touch, and smell was of fundamental importance. Even the negative evidence of the senses could be of great use. It enabled certain possibilities to be ruled out, and the field of alternatives to be correspondingly narrowed. It remained for the mind to balance the evidence, sometimes apparently contradictory, of the senses. A small and insignificant difference in the initial data might prove of enormous consequence when it had to turn the scale in forming a conclusion. At the end of his brief address, Mr. Waring emphasized the value of logic and of carefulness in deduction.

Dr. Raymond Crawford moved a vote of thanks to the Vice-Chancellor, which was seconded by Sir Lenthal Cheate.

#### LONDON SCHOOL OF MEDICINE FOR WOMEN.

The opening of the new session of the London (Royal Free Hospital) School of Medicine for Women took place on the afternoon of Monday, October 1st, when the inaugural address was given by Sir Humphry Rolleston, K.C.B., President of the Royal College of Physicians of London, on "The problem of success for medical women." The address is printed in full in the opening pages of our present issue. The audience included many members of the teaching and hospital staffs and a large number of past and present students. The report of the Dean, Dr. Louisa Aldrich-Blake, showed that there has been a decrease in the entry of students; the total number is now 438, of whom 53 have entered this session. The report drew attention to the ample opportunities for professional practice now open to experienced women, and noted with gratification the success of qualified students of the London School of Medicine for Women in obtaining appointments. The vote of thanks to Sir Humphry Rolleston for his address was proposed by Dr. A. G. Phear, Physician to the Royal Free Hospital, who remarked that a visit to the rowing, tennis, swimming, and social clubs in connexion with the school would show that the woman medical student knew how to play as well as how to work.

#### THE MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE SOCIETY.

The annual general meeting of the Medical Sickness, Annuity, and Life Assurance Society, Limited, was held at the offices of the company, 300, High Holborn, W.C.1, on October 1st, when Dr. F. J. ALLAN was in the chair.

The CHAIRMAN said that the members of the society congratulated themselves on the steady progress made during the year, as shown in the annual report, which had been circulated. In the sickness and accident branch the number of policies issued was 353, an increase of 113 over the previous year. During the year £19,072 had been paid out on account of sickness and accident claims, a decrease of £1,200 as compared with the preceding twelve months.

In accordance with the resolution adopted at the last annual meeting, bonuses amounting to £15,402 had been returned to members. Letters were constantly being received from members expressing their grateful thanks for the assistance which the society had rendered to them while incapacitated for the sympathetic way their claims had been dealt with, for the absence of unnecessary restrictions, and for prompt settlement. Many of the letters expressed regret that so many medical men did not take advantage of the excellent terms offered by the society. Some of the applications for sickness and accident policies were received through recommendations of existing members, and the chairman urged all members to assist by bringing the benefits of the society to the notice of their friends, and to point out the advantages of being insured in a society formed by and for doctors and dentists on mutual lines.

The life assurance branch showed a gratifying increase of about 30 per cent. over the preceding year; the sum assured amounted to £77,950 net, which clearly showed that the profession was realizing the value of the policies which the society offered at such reasonable rates of premium. The claims through death were well within the expectation. Members were asked to study carefully the varied methods of life insurance set forth in the different tables in the latest prospectus, and the society was always willing to consider the wants of applicants who might desire some special form of insurance other than those shown in the tables. Over £5,000 was being paid out in annuities to members over 65, and it was expected that that amount would increase for some years. Only two annuities had been taken out during the year, but that was not a matter of regret, as, owing to the prolonged life of annuitants, annuity business was considered by many life assurance companies to yield little if any profit at the rates at present charged, which were based on experience of longevity as it existed forty years ago, when life was shorter than it is now. It was anticipated that the rates for annuities would be increased as the result of an investigation by a committee of actuaries, whose report was expected to be shortly issued.

The rate of interest earned on investments was £3 14s. 6d. per cent. after deduction of tax, which was 3s. 6d. more than last year. The greatest care was always exercised in selecting securities of the best class.

In concluding his address the chairman said that the board desired to express its appreciation of the way in which the business of the company was conducted by the staff; he moved the reception of the annual report.

Dr. G. PORTER, in seconding the adoption of the report, referred to the fact that when he joined the society the funds amounted to £75,000, whereas at the present time they had over £360,000. He considered that the directors had to be very much congratulated.

In reply to an inquiry the CHAIRMAN stated that about sixty women medical practitioners had joined the society.

The motion for the reception of the report, having been put to the meeting, was carried.

The next item of business was the election of two directors, and as Dr. F. J. Allan and Dr. W. K. Sibley had had to retire, but were eligible for re-election, Dr. MARLEY took the chair. On the motion of Sir WILLIAM WILCOX, seconded by Dr. HARVEY HILLIARD, the two retiring directors were re-elected. Dr. Allan thereupon reoccupied the chair.

Messrs. Harber, Sturges, and Fraser were reappointed auditors for the ensuing year.

With reference to a resolution adopted at the last annual general meeting granting extra remuneration to the chairman and directors, which had not been carried out since it was found that proper notice had not been given, it was now proposed by Dr. CAMPBELL and agreed that remuneration in addition to that mentioned in Article 28 of the company's Articles of Association be paid to the directors as follows:

To the chairman and each director the sum of £1 1s. 6d. every attendance at the meetings of the board or of committees of the board and general meetings.

The following resolution, moved by Dr. D. FORSYTH, and adopted:

That with a view to carrying out the resolution passed at the last annual general meeting, a sum of £552 6s. in addition to the ordinary remuneration, be voted to the directors for their past services.

On the motion of Dr. VINNAGE a hearty vote of thanks was accorded to Dr. Allan for his services in the chair.

girls to normal womanhood and motherhood, it is more in sorrow than in anger that I see the unpopularity of the operation with many foreign obstetricians and their failure to follow the three simple rules above enumerated, which are essential for success.

ANÆSTHESIA AND ANÆSTHESIA.

Before I proceed to consider Caesarean section for constricted pelvis it may be well to review the development of the antiseptic treatment which has revolutionized this and other operations.

In 1772 Charles White of Manchester published a *Treatise on the Management of Puerperal and Lying-in Women*. In this work White speaks of puerperal fever as a putrid fever which is contagious and arises from putrefaction of retained products or from the air of lying-in wards. White's contribution to the study and treatment of puerperal fever was an important one and has been dealt with very fully by Professor Adam in his *Lloyd Roberts Lecture*.

In 1843 Oliver Wendell Holmes published in the *Quarterly Journal of Medicine and Surgery* a paper on "The contagiousness of puerperal fever," in which he adduces strong evidence of the contagiousness of the disease and points out effective means of preventing it.

He specially mentions changing the clothes and washing the hands with chloride of lime after visiting cases of puerperal fever; he reports that by adopting these precautions a doctor was able to attend other cases of labour which ran a perfectly normal course.

In 1846 Ignaz P. Semmelweis became assistant in the lying-in wards of the General Hospital in Vienna. From 1784 to 1822 these wards had been under the care of Zeller (1784-89) and Boer (1789-1822) and the mortality from puerperal fever had been 1.25 per cent. over the whole period. Under Boer's successor Klein medical students were allowed to practise anatomy

and to dress suppurating wounds while attending cases of labour, and Semmelweis noticed that the mortality was much higher in the wards attended by the medical students than in those attended by the midwives. In the five years before Semmelweis's appointment the mortality in the students' wards had risen from 6.56 to 9.92 per cent., while that in the midwives' wards had fallen from 5.58 to 3.33 per cent. Semmelweis adopted the method of washing the hands with chloride of lime, with the result that the rate of mortality fell from 8.3 to 2.5 per cent.

It is the undying merit of Semmelweis to have pointed out that puerperal fever arose not only from infection from corpses, but from any putrefying organic substances. What purification was due to was shown by the researches of Pasteur in 1869, and Lister in 1867 gave to the world his antiseptic treatment, which laid the foundations of the modern aseptic surgery, by which the danger has been almost completely removed from operations which a few years ago were uniformly fatal.

The introduction of *anæsthesia* by means of ether (Morton, 1846) and chloroform (Sir James Simpson, 1847) years ago were uniformly fatal. The introduction of *anæsthesia* by means of ether almost completely removed from operations which a few years ago were uniformly fatal.

Fig. 1.—Medal struck in honour of Edvard Porro to commemorate the twenty-fifth anniversary of the performance of the first amputation of the uterus after Caesarean section (1870).

Fig. 2.—Headpiece of Sacombe's *Éléments des accouchemens* (1820) depicting Hercules destroying the Caesarean.

CAESAREAN SECTION.

Caesarean section has always been interesting, and never more so than at the present day. The origin of the word "Caesarean" is unknown. On the supposed birth of Julius Caesar by means of this operation, based on an error in the translation of a passage in Pliny, Sacombe has given his opinion in the following terms: "Pliny was a lying historian whom it would have cost no more to split the belly of Aurelia with his pen in order to deliver Caesar than to split the rocks with which he tried to open up a way across the Alps for the troops of Hannibal!"

The first volume of the *Mémoires de la Société de Médecine de Paris* contains a most learned paper in the form of a letter addressed to Letson on the character of Aesculapius. The writer of the letter describes the birth of Aesculapius by Caesarean section as mentioned in Ovid's *Metamorphoses*, *namque parentis natus flammis utero Chironis in altum*. Despite these illustrious examples, Caesarean section attained but little popularity until the end of the eighteenth century, although it had been practised on the Continent, in England it was twenty years after the foundation of our Society—in 1793—that the first successful operation was performed on a living woman by Barlow of Bolton; the child did not survive.

Ambroise Paré (1510-1580), having seen two Caesarean sections performed by his pupil Guillemeau, with fatal results to the mother, was opposed to the operation: "Je ne conseillerois jamais de faire tel centre où il y a si grand péril sans nul espoir." In 1581 Rousset had published the first work on the subject under the title *Hystérotomologie*.

In 1595 Scipione Mercurio had recommended the operation. He had seen patients on whom it had been performed in Toulouse, where he said it was as well known as bleeding for headache. He gave an illustration of the operation and recommended that the incision should be made to the right of the middle line in order to avoid the spleen. At the time our Society was founded there was a wide-spread desire amongst obstetricians to avoid the horrible craniotomy which at the end of the eighteenth century was performed frequently, especially in England. The most eminent of these obstetricians was Jean Louis Baudelocque. On the "17 ventose de l'an IV" (1796) Baudelocque performed Caesarean section on a patient who had previously had a living child at term; the patient died three days after

Professor Currie had a distinguished career as a student in various universities. In 1891 he graduated M.A. at Edinburgh University, and thereafter proceeded to Lincoln College, Oxford, with a scholarship. He took a first class in classical honour moderations, and was presented to an exhibition. He graduated B.A. there in 1896, and M.A. in 1910. His medical education was obtained in Glasgow University, where, after a course of much distinction, he qualified as M.B., Ch.B. with commendation in 1898, and, in 1910, M.D. with high commendation. After a year's training in the Glasgow Royal Infirmary as resident physician and surgeon he took up medical practice in Birmingham, and while there he took the D.P.H. in that University. He returned to Glasgow and held a resident appointment in Belvedere Fever Hospital under the Glasgow Corporation. From this period his work has been confined to preventive medicine. In 1906 and 1907 he acted as M.O.H. for the counties of Stirling and Dumbarton in the absence of Dr. John C. McVail. Thereafter he held in succession similar posts in the city of Chester and in the counties of Fife and Kinross. In 1912 he entered the service of the National Insurance Commission in Scotland, where he remained, except for a period of three years' war service, till 1919, when he passed into the service of the Scottish Board of Health. In August of last year he was appointed Professor of Preventive Medicine in Kingston, Ontario. He has at various times contributed largely to medical literature, especially on public health subjects, and he is the author of several exhaustive reports on similar matters under Government departments. He was responsible for the history of medical recruiting in Scotland during the war, entitled *The Mustering of Medical Service in Scotland*, which was published in 1922, and reviewed in our issue of January 6th, 1923 (p. 24).

## Ireland.

### MINISTRY OF HEALTH IN THE IRISH FREE STATE.

RISE out of a discussion in the new Dail on the appointment of Ministers, Sir James Craig, M.D. (Dublin University), expressed much regret that nothing had been said about the creation of a Ministry of Health. "The medical profession, at all events, had been looking forward with some hope that in the new appointments to be made in the present Dail a Ministry of Health would be among the ministries formed. He had not urged this matter very strongly because of the expense connected with it. It was not desirable to multiply the number of ministries, but, as he said on a past occasion, surely the health of the people was of more importance than the fish in the rivers and in the seas, for the protection and improvement of which a ministry had been established. It was generally realized, at all events, that they could not have a healthy population if the health of the people was not looked after, and he said deliberately that the public health of the country was in a very serious condition. Sir James Craig added that he was not going to press this matter at the present moment, because he felt like an orphan in that assembly. He was not going to press the President to add to his ministries that other Ministry of Public Health, but he was going to suggest that the Government should do the next best thing, and that a Public Health Department should be formed within the Ministry of Local Government, and that there should be a parliamentary secretary in the Dail who would be responsible for the Public Health Department of the Government. Sir James Craig then expressed his admiration for the work done as Minister for Local Government by Deputy Blythe, who had made himself thoroughly acquainted with the matters relating to the public health of the country, and proposed to introduce a Public Health Bill, which was one of the bills delayed owing to the work that the Government had to do before the dissolution of the last Dail. It would be a difficult matter to get a Minister able to follow in the footsteps of Deputy Blythe. Perhaps the President would give some encouragement by saying that the Government

would form such a department within the Ministry of Local Government, and that some deputy would be responsible for public health matters in the Dail.

Mr. Ernest Blythe (late Minister of Local Government), in reply, said, with regard to the remarks of Deputy Sir James Craig, he thought it should be clear there could be no question of having a Department of Public Health and a Department of Local Government at the same time. The Department of Local Government was really, as far as it went, a Department of Public Health. Nearly all the activities of that department, except roads, were concerned with public health. Housing and the relief of the necessities were really matters for a Department of Public Health. The medical charities or the provision of medical relief was also a matter for the Public Health Department. In the Ministries Bill, which it was not possible to bring before the Dail, he believed it was the intention that the name should be Department of Local Government and Public Health, and that the National Insurance Commission would come in under the department. It would then be merely a matter of choosing a name. It could be the Department of Health, or the Ministry of Health, or any other name that was suggested. It was intended really to give a substance to the Department of Health, with one or two functions added to it for administrative convenience.

### EARLY TREATMENT OF MENTAL DISORDERS.

In his report for the year 1922, Dr. S. J. Graham, medical superintendent of the Belfast District Asylum, emphasizes the value of early skilled mental treatment in hospital in improving the chances of recovery from mental disturbances. He remarks that the Lunacy Law, as applicable to Ireland and as at present framed, does not encourage early treatment. It is illegal to receive as voluntary boarders early uncertifiable, mentally afflicted patients, also certifiable harmless patients (who are willing to submit to such treatment) without certification. Dr. Graham maintains that if the lunacy laws were amended to meet such conditions, the stigma of certification, so much dreaded by patients and their relatives, would be removed. This would enable the patients to be advised and encouraged to submit to such treatment and so facilitate early recovery. He expresses his warm approval of the "Voluntary Boarders" section of the Mental Treatment Bill, recently introduced into the Imperial Parliament by Lord Onslow, and urges that all the privileges thus conferred should receive the attention of the Government of Northern Ireland, so that the mentally afflicted in Northern Ireland may receive the same benefits as those mentally deranged in England and Scotland.

## Correspondence.

### THE SOCIAL ASPECTS OF TUBERCULOSIS.

SIR,—In the course of an exceedingly interesting opening paper on "The social aspects of tuberculosis, with special reference to its infectivity," which appears in your issue of September 22nd, there occurs, on page 513, a statement which Dr. Jane Walker will probably pardon me for referring to. The point under discussion is the occurrence of massive infection and the bearing which overcrowding in smaller-sized houses has on the frequency of this. The sentence reads:

"Several points are emerging which seem to show that overcrowding even is not quite so responsible for cases of tuberculosis as we thought it was. For example, whether people live in one room or in six, as far as Glasgow is concerned, does not appear to make much difference in the incidence of tuberculosis."

I am not quite sure whether Dr. Walker has based this view on some statement in one of the annual reports issued by this department or on the rates contained in a paper issued about ten years ago, but it may be well if I quote from both sources in order that they may be the more readily compared. The house distribution of the cases is taken from the notifications of 1920-23, while the death rates are calculated on a standardized house population as described in the paper on "The house, etc.," above referred to.

Finally, the writer of the article appeals for protection of women in childbirth against the ill judged enthusiasm of the untrained obstetrician. It is evident that Caesarean section, which Sacaboe thought he had put an end to in 1798, has shown marked evidence of revival, and his hydra has developed "heads" which were non-existent in his day. The performance of Caesarean section for cases of placenta praevia, accidental hemorrhage, malpresentations, and clampsia is being overdone, though not to the same extent as for "contracted pelvis." It is sad that such a beneficial operation as Caesarean section, which has been developed to such a pitch of perfection, that a woman, however deformed, can be delivered safely to herself and child, should be brought into disrepute by being performed in cases for which it is unnecessary.

*Antenatal Diagnosis.*

I have endeavoured to show some of the changes which have occurred in the treatment of contracted pelvis in the lifetime of the Medical Society of London. Further improvement of the treatment depends on more accurate measurement of the pelvis and foetal head, probably by means of x rays. Every woman should have her pelvis measured to see if she is fitted for child-bearing. During pregnancy she should be examined at the thirty-fourth week to ascertain the presentation of the child and its size relative to that of the pelvis. If the pelvis is contracted, it should be treated by one of the methods suitable for the particular case. Of these methods at the present time, in my opinion, induction of premature labour is employed too little and Caesarean section too much. As opinions are of less value than facts I give the results of three years' practice at University College Hospital, where the routine mentioned above has been adopted. In the three years (1920, 1921, and 1922) 5,647 women were delivered. Of these, premature labour was induced for contracted pelvis 113 times, all the mothers and 101 of the children surviving. Caesarean section for contracted pelvis was performed 32 times, all the mothers and 30 children surviving. Craniotomy was performed 4 times (twice for dead children and twice for hydrocephalus); the four mothers recovered. Forceps were used (for various reasons) 169 times (that is, in less than 3 per cent. of the cases), all the mothers recovering. I am indebted to the obstetric registrar, Mr. Leslie Williams, for these figures.

*Remaining Risks of Caesarean Section.*

Caesarean section entails risk of haemata, of adhesions, and rupture in subsequent pregnancy. These risks are probably avoidable in aspic cases by proper suturing and sutures. How great these risks are can only be ascertained when obstetricians publish all their cases instead of a selection of cases done in favourable conditions before or in the early stages of labour, or cases being treated by craniotomy or hysterectomy. The sterilization of a woman after Caesarean section in an uncomplicated asepic case is, in my opinion, not justifiable; in complicated cases hysterectomy is sometimes required.

*Conclusion.*

In conclusion, I hope I may be pardoned for bringing a somewhat technical subject before the Medical Society of London. In the past some hard things have been said of obstetricians; in recent days, however, they have been commended as integrators of medicine. Agreeing with Sir Clifford Allbutt as to the importance of that integration, I have placed my views before a Society which by its constitution and practice is the best example of the advantage to be derived from discussion of medical subjects by physicians, surgeons, and general practitioners, of whose assistance the medical and surgical secretaries, of whose devotion to the interests of the Society I have already evidence, I hope to be kept mindful of that integration at the meetings over which it will be my privilege to preside.

REMARKS.  
"London Medical Journal, March, 1923." *Journal, Obstet. and Gyn. of the British Empire, 1926.*

PART II.—THE NERVE IMPULSE: THE IMPORTANCE OF THE RECEPTORS: AND THE PRODUCTION OF PAIN.

THE REGULATING AND REFLEX PROCESS.  
P. T. HERRING, M.D.,  
PROFESSOR OF PHYSIOLOGY, ST. ANDREW'S UNIVERSITY, AND  
PHYSIOLOGIST TO THE ST. ANDREW'S INFIRMARY FOR CLINICAL RESEARCH.

The anatomical unit of the nervous system, the neurone, consists of a nucleated cell body and one or more processes, one of which is always an axis cylinder. The other processes, when present, are dendrons, and frequently branch up into numerous small branches known as dendrites. The function of the whole unit—dendrons, cell body, and axis cylinder—is to conduct the nerve impulse. The conducting element is a watery fluid containing protein and lipids in solution, and possessing the physico-chemical attributes of living matter in this condition. No fibrils can be seen in the living neurone, though they appear in the dead nerve after certain methods of fixation and staining have been employed. The cell body and dendrons contain a store of reserve energy in the form of nucleoprotein, which, when coagulated by certain fixatives and suitably stained, gives rise to the so-called Nissl bodies. The nucleus presides over the nutrition of the whole neurone and maintains it in a condition suitable for carrying the nerve impulses. But the presence of the nucleus and cell body is not essential for the passage of the nerve impulse, for, if cut off, the remainder of the neurone can still conduct for a limited time before it dies. The nerve impulse, when excited by artificial means in an isolated nerve fibre, travels in both directions from the point of stimulation, but in the intact nervous system the nerve impulse travels normally in one direction only. The synapses between the neurones are irreciprocal, possessing a valve-like action which prevents any accidental impulse passing into the next neurone. The synapse only allows a nerve impulse to pass from the endings of the axis cylinder of one neurone to a dendron or cell body of the next neurone. Consequently the nerve impulse can only take the one direction through a physiological unit, and the neurone, when in a state of activity, only transmits its impulses in a forward direction. The cell bodies of the peripheral afferent neurones are found in the ganglia on the posterior roots of the spinal cord, and in the corresponding ganglia on the cranial sensory nerves. The peripheral nerve fibre of each cell, though it possesses an axis cylinder, is morphologically the dendron of what was originally a bipolar cell. This dendron runs directly into an axon at the T-shaped junction near the body of the nerve cell in the ganglion, and there is evidence that the nerve impulse passes directly over this junction. Some of the spinal ganglion cells have small intracapsular dendrons, and consequently nerve impulses can reach the neurone through them, in which case the cell may also be concerned in conduction. But little is known about the function of the intracapsular dendrons of the spinal ganglia. Their presence, however, indicates that a certain amount of analysis and redistribution of nerve impulses may take place in these ganglia. In the olfactory nerve the cell body of the first afferent neurone lies in the olfactory membrane itself, and its dendron is a specialized portion of the cell which forms a tiny projection on the surface of the membrane. In the auditory and vestibular nerves the cell bodies are bipolar, forms arborizations among the cells of the sense organs which are developed as special receptors. Little is known about the afferent neurones of the viscera, but there

"The expense of this research was in part met by a contribution from the Medical Research Council."

As to the quackery that flourishes in both Canada and the U.S.A., I was informed by one of the leading medical men in Seattle, Oregon State, that there were men in actual general medical practice in Seattle, describing themselves as "hydrotherapeutists," whose sole claim to medical knowledge was the fact that they had been attendants at Turkish baths, and who were permitted by the laws of the State to attend women in childbirth and also issue death certificates.—I am, etc.,

VINCENT P. NORMAN,  
F.R.C.S. Edin., D.P.H. Lond., L.M.C. Canada.

Bradford, Sept. 24th.

#### BETEL CHEWING AND CANCER.

SIR,—Dr. Archibald Leitch, in his paper on the "Causes of cancer" (BRITISH MEDICAL JOURNAL, July 7th, 1923), says, with regard to betel chewing as a possible cause, that "the number of cases of cancer of the cheek actually observed by any one medical man [in Southern India and the Philippines] seem to be surprisingly few," and goes on to state that this "should make us cautious in accepting this [betel chewing] as an instance of cancer due to tobacco, or even as an example of an irritation cancer at all" (italics mine).

Now, I with many other surgeons in Ceylon firmly believe that betel chewing furnishes as good an example of irritation cancer as one could wish to see. Whatever may be the experience of medical men elsewhere, it cannot rightly be said of Ceylon that "the number of cases of cancer of the cheek seen by any one medical man are surprisingly few"—that is, by any one medical man with full opportunities to judge; for these cases gravitate to the large hospitals, and the surgeons of these institutions, rather than general practitioners, have the best chance to form an opinion of their frequency.

I am sorry I cannot lay my hands on figures just now, but I do not think I exaggerate when I state that the cases of cancer of the cheek coming to the General Hospital, Colombo, in any one year are at least as numerous as the number of weeks in a year; and this despite the dread the people of this country have of operations and the breezy optimism of *vedavalas* who keep promising cures until the patient is dead.

Even so, it may be argued, the number is very small compared with the thousands who indulge in betel chewing. Still it is numerous enough to suggest more than a mere coincidence and to drive home a strong conviction. Why deny to betel chewing what one is so ready to credit to paraffin and arsenic? Are not cases of cancer due to these also relatively few?

Cancers of the cheek are among the commonest malignant growths encountered in Ceylon; they are as common in women as in men, betel chewing being a luxury not limited to sex.

Dr. Leitch very rightly draws attention to the fact that "the betel preparation is a crude mixture of areca leaves [I presume he means either betel leaves or areca nut], lime, and probably other substances as well as tobacco, and the effect of these accessories cannot be discounted." I am inclined to think it is the lime that provides the continuous irritant, though the potency of the crude tobacco should not be under-estimated. Cancer of the cheek as one sees it here almost invariably begins as a leucoplakia or a roughening of that part of the buccal mucous membrane that lies in contact with the molars and pre-molars, which are always more or less discoloured and coated with rough deposits of tartar and lime providing a sandpaper-like surface. One has but to see a series of such cases to be convinced that here we have cause and effect.

Carcinoma of the penis is another astonishingly common form of malignant disease in this country. Between June, 1911, and June, 1915, no fewer than 91 cases were operated on by me at the General Hospital; and I was but one of three surgeons. Here the specific irritant seems to be the pent-up smegma, caked and disintegrated; for congenital phimosis is the almost invariable accompaniment. Carcinoma of the penis is never seen in Moors who practise

circumcision; it is most common among Cingalese cultivators. Here, too, the disease begins as a leucoplakia of the glans and preputial mucous membrane, passing on to roughening, erosion, and craggy ulceration or exuberant growth.—I am, etc.,

Colombo, Sept. 6th.

R. L. SPITTEL.

#### ETHER VERSUS CHLOROFORM.

SIR,—Dr. C. F. Hadfield's reply (September 22nd, p. 543) to my letter is very welcome, and makes it clear that the correspondence ought to be prolonged a little, because open ether and its modifications is supposed to ensure a factor of safety for the average patient when administered by the average practitioner. In such circumstances the views of the average surgeon are bound to come in. The question centres round muscular relaxation, and until this is measured by some standard method the facts will never be known and we cannot profitably argue about them. As Dr. Hadfield says, "many surgeons are tonometers of excessive delicacy"—especially on a bad day! The order of onset of relaxation in the sets of muscles will require to be determined both for ether and for chloroform. Personally, I see no objection to using a tonometer in or near the wound if it can be sterilized and does not get in the way, and as this would render the study more scientific it ought to be done.

I understand, for instance, that the combination of morphine and chloroform was abandoned by anaesthetists long ago, and dangerous, as it produces in the patient a condition of narcosis with muscular rigidity, and a slowing of respiration, followed generally by inspiratory stridor. In this condition the patient may appear to be deeply anaesthetized, but is anything but ready from the surgical point of view, being, as Dr. Hadfield says, "not under any anaesthetic," but rather in a transition stage of a sequence. Usually it is an emergency case in which morphine has been given, unknown to the anaesthetist, for pain or transport; given empirically, and not according to body weight. If the induction has been by ether or ethyl chloride, or if ether continues the sequence and the patient is an alcoholic or otherwise not a suitable subject for ether, the dilemma may be a very real one. Chloroform intensifies the symptoms already detailed and the respirations become slowed and ultimately cease. The way out appears to be to increase the concentration of ether vapour by the use of apparatus or to add a small quantity of a third anaesthetic such as ethyl chloride. A tonometer in these circumstances would further indicate the prevailing state and show whether the increasing concentration of ether was likely to be sufficient. But there is such a large personal factor in every case of general anaesthesia that one anaesthetist will pass to the later stages in one way and another in another way according to the case.

Dr. Hadfield mentioned a point I left out. That bronchitis may be due to the disease and also to the operation, no one will deny. There is a difference in this respect between the upper and the lower abdomen, and between septic and aseptic cases, but even making these allowances the bronchitis rate in abdominal cases generally seems to me to be greater now than it used to be when chloroform was used more frequently.—I am, etc.,

G. H. COLL.

Aberdeen, Sept. 25th.

#### TESTS FOR DRUNKENNESS.

SIR,—In your issue of September 15th Dr. L. A. Parry (p. 487) writes to seek information on the question "Drunk or sober?" In my little work *Practical Forensic Medicine*, published by Lewis of Gower Street, I dealt with the question at some length. The book was killed with the question at some length. The book was killed, I think, in the war, because I have heard nothing of it since, and it deserved death, being sadly out of date. If Dr. Parry will borrow the work from the British Medical Association library (I do not advise him to buy a copy) he will find in it the result of twenty years' experience in the subject.—I am, etc.,

GRAHAM GRANT.

London, W.C., Oct. 1st.

and Surgery, and that the obstetricians of to-day owe no small debt of gratitude to his pioneer work in this respect.

In practice Sir Halliday Croom's success was conspicuous. He was called far and wide as a consultant and operator—to Rome, Paris, London, and all over Great Britain—while his fame as an obstetrician attracted many distinguished patients to Edinburgh who sought the advantage of his services. In spite of the claims of such a practice, however, and of his almost passionate absorption in teaching, he found time for much professional writing. His papers were nearly all clinical and practical, and they range over almost the whole of practical midwifery and gynaecology. His observations on *The Bladder during Parturition* and his *Handbook of Minor Gynaecological Operations and Appliances* were both published in book form, and the latter had a great success, running through several editions in this country and in America. In all he wrote some hundred articles, addresses, and monographs, all of which had their special points of interest and importance. Amongst the more notable are those on "Retention of Urine in the Female," "The Causation of Face Cases," "The Systematic Use of Antiseptics in Midwifery," "Dysmenorrhoea and Sterility," "The Diagnosis of Early Extra-uterine Gestation," "Caesarean Section in Eclampsia," "Mittelschmerz," "Senile Uterine Catarrh," "Exophthalmic Goitre in relation to Pregnancy and Labour." These are but a few amongst many, but they serve to show the catholicity of his observations and writings.

Sir Halliday Croom was a Fellow of the Royal Society of Edinburgh, of the Royal College of Physicians and of the Royal College of Surgeons of Edinburgh; and it was in 1902 when he was President of the latter College that he received the honour of knighthood. He was throughout his whole professional life a devoted Fellow of the Edinburgh Obstetrical Society, and one of the most regular contributors to its debates. The fact that he was elected to the presidential chair of the society three times shows the position which he held in the hearts of his colleagues. His eminence in his specialty led also to his election as President of the British Gynaecological Society, whilst among the foreign societies of which he was appointed an Honorary Fellow were the American and the Belgian Gynaecological Societies. He was President of the Obstetrical Section of the British Medical Association Meeting at Carlisle in 1896. Dublin University conferred upon him its Honorary M.D., while on his retirement his Alma Mater sealed her acknowledgement of his life-long services by making him an Honorary Doctor of Laws amid a scene of unequalled spontaneous enthusiasm on the part of the student audience.

Amongst his many services to the profession and to the cause of midwifery must not be forgotten his work in connexion with the Central Midwives Board for Scotland. He gave the full weight of his influence and authority to the movement which eventuated in the passage of the Midwives Act for Scotland, and he was unanimously appointed the first Chairman of that Board, serving on it from the time of its inception in 1915 until 1920.

Sir Halliday Croom married in 1875 Miss Anna Isabella Walker, and one son and three daughters were born of the marriage. His wife died in 1898, and this sorrow was a great blow to him. His eldest daughter ably took up her mother's duties in the household and acted as her father's hostess for many years until her marriage to Dr. A. J. Beatlie. Her premature death in 1913 was therefore a second very severe blow which aged him considerably in the eyes of his friends. The two younger daughters and his only son survive, the latter, David Halliday Croom, being a well known physician in Edinburgh.

Sir Halliday Croom was a man of extraordinary personal attractiveness, and of an almost womanly charm which was so spontaneous and innate as to elude any attempt at analysis. His tall graceful figure, always immaculately clothed, was one of the best known public figures in Edinburgh. His courtly and aristocratic appearance were but the outward marks of a nobly sensitive nature. He was a man of extraordinary courtesy to rich and poor alike, quick in sympathy with anything in the nature of suffering, hating cruelty, hypocrisy, and disloyalty above all things. His sensitiveness made him somewhat quick in temper and

impulsive in action, but his wrath was never long sustained because his nature was essentially generous. His vivacious sense of humour was delightful, and found expression in whimsical and unexpectedly forcible phrases which gave extraordinary point to his teaching and to the stories with which he used to delight both his classes and his friends and guests. He was an inimitable and most hospitable host and enjoyed nothing better than having his friends round him at dinner. A true son of the manse, he never lost the impress of the early days and the early teaching. He was a man of deep but simple beliefs, to which he clung with unalterable loyalty. The affairs of the United Presbyterian and subsequently of the United Free Church always claimed a generous share of his interest, and like a true Scot he loved nothing better than a good-going theological discussion.

Sir Halliday Croom was buried in the Dean Cemetery on Saturday, September 29th, in the presence of a large concourse of his fellow citizens, representing every class and every profession and activity, and on the Sunday a largely attended memorial service was held in Lauriston Place United Free Church, his father's old congregation, in which he himself had served as an elder for many years.

Dr. JAMES HAIG FERGUSON (Edinburgh) writes:

I have been asked as a former assistant of the late Sir Halliday Croom to give a short appreciation of my old chief, and it is with a full heart that I do so. I would recall him as a teacher, as a physician, as a man, and as a valued friend. Sir Halliday Croom's name will go down to posterity as that of a great teacher. As such he was in the first rank, and it is safe to say that no more successful or popular teacher, whether in the lecture room or by the bedside, has existed in the Edinburgh Medical School in this generation. His didactic method was always impressive, his enthusiasm was contagious, and his unflinching sense of humour and lightness of touch, coupled with a wonderful vivacity, all combined to make his lectures telling and effective. Teaching was ever a joy to him; it seemed to come to him so easily, but only those behind the scenes knew the infinite trouble he took to prepare his systematic lectures even down to the smallest details. He put his whole mind and soul into their preparation and delivery. Even in his younger days at the end of a lecture he was often worn out by his efforts, though it all appeared so spontaneous and easy to his hearers at the time. While often physically exhausted by his teaching, he was mentally exhilarated and he often used to say that he seemed to absorb fresh mental stimulus and vitality from the crowded benches of eager and enthusiastic young minds whose attention he never allowed to flag for an instant. His illustrations and apt remarks were always striking, and culled as they were from a ripe experience they have become (many of them) aphorisms indelibly fixed in the minds of the thousands who, in the course of his fifty years of teaching, have had the privilege of passing through his hands. In truth he had the great gift of making the dry bones live. Nothing was such a joy to him as the appreciation of his students, and the pleasure which this gave him brought out all that was best in the man, and showed the unaffected simplicity of his real nature.

Croom's enthusiasm for his department has undoubtedly done much to raise obstetrics and gynaecology to the high place they now hold in medicine and to rescue them from the neglected and somewhat despised position to which in the times past they were apt to be relegated. As a young graduate and while still assistant to the late Sir Alexander Simpson he rapidly acquired a large and lucrative general practice. Gynaecology was then in its chrysalis stage, but as it gradually emerged (and Croom was one of the pioneers who promoted its development) he gradually dropped general practice. He used to say that he regarded this preliminary experience as having been of great value to him in after life. Few certainly could deal with patients more successfully and tactfully than he did and he seemed to have an intuitive knowledge of their thoughts and feelings which at once put them at their ease and won their confidence and regard to a remarkable degree. He also quickly gained the confidence of the profession by his skill

FIG. 2.—Showing internal aspect of bone.

The death took place at Macduff, Banffshire, on September 22nd, of Dr. J. I. McARTHUR, at the age of 71. James Irvine McArthur was educated at the University of Aberdeen, where he graduated M.B., C.M. in 1882. Over forty years ago he went into general practice at Gamrie, Banffshire, where he remained until his retirement some three years ago. Although he had one of the most extensive practices in the county he also superintended the working of two farms which had the reputation of being the best managed in the district. He was medical officer to the Gamrie and King-Edward Parish Councils, and for many years was surgeon lieutenant to the Banffshire Artillery Volunteers. He was a justice of the peace for the county of Banff, and a member of the British Medical Association.

We regret to record the death of Dr. ALEXANDER REID STODDART, of Fishergate, York, on September 25th, after a long illness due to war service. He was the eldest son of the late Dr. John Stoddart of Kirkcaldy, Fife, and received his medical education at Edinburgh University, where he graduated M.B., C.M. in 1887; he afterwards studied at Prague and Vienna. After holding the appointment of house-surgeon at Edinburgh Royal Infirmary he went into practice at York in 1891, where he was a successful practitioner and popular with his professional colleagues; some years ago he was elected president of the York Medical Society, of which he was also honorary librarian. He was a member of the British Medical Association. Dr. Stoddart joined the 5th (York) Battalion of the West Yorkshire Regiment in 1896, in which he attained the rank of surgeon major. During the great war he held a commission in the R.A.M.C., and served in France; in 1916 he was mentioned in dispatches. When he returned to York at Christmas, 1918, it was evident that the war had left its mark upon him, and he suffered from ill health up to the time of his death. The funeral service in St. Martin's Church on September 29th was attended by a large congregation, which included most of the medical practitioners in York. Dr. Stoddart is survived by his widow, four daughters, and one son.

We regret to record the death on September 18th, in his 70th year, of Dr. W. H. SMITH of Boston, Lincolnshire, the son of Dr. B. A. Smith, who practised for over fifty years at Sibsey. William Henry Smith received his medical education at St. Mary's Hospital, London, where he obtained the L.S.A. in 1876 and M.R.C.S. Eng. in 1877. He was house-surgeon at the Beckett Hospital, Barnsley, and at Hull General Infirmary, before going into practice at Revesby and later at Boston. Dr. Smith was appointed honorary surgeon to the Boston Hospital in 1897, and on his retirement in 1916 was appointed consulting surgeon. During the war he acted as medical officer to the Holden House Red Cross Hospital. He held the appointment of medical officer to the Boston Board of Guardians for thirty-three years. He was one of the oldest members of the Holland Division of the British Medical Association, of which he was chairman for some years, and representatives of the Division attended his funeral. Dr. Smith was also a member of the Panel Committee. He was unmarried.

## Universities and Colleges.

### UNIVERSITY OF LONDON.

The Vice-Chancellor, on behalf of the University, addressed on September 11th to His Excellency the Japanese Ambassador a letter of sympathy with the Japanese nation in the overwhelming destruction of life and property experienced during the calamitous earthquake. His letter contained the following passage: "We remember at this sad hour the many and various ties which link our countries and their universities, and we most earnestly hope that your country will emerge successfully from this ordeal to continue her great and beneficent mission of civilization and culture." A message of appreciation in reply was received from the Japanese Embassy, thanking the University of London for its expression of sympathy.

The Semon lecture for the year 1922-23, entitled "The advancement of laryngology," will be given at the rooms of the Royal Society of Medicine, 1, Wimpole Street, by Dr. A. Logan Turner, lecturer in laryngology, otology and rhinology in the University of Edinburgh, on Thursday, November 1st, at 5 p.m. The chair

will be taken by Mr. Charles A. Parker, F.R.C.S. Admission is free, without ticket.

The Stansfeld lecture for 1923-24 will be delivered at Bedford College in February, 1924, by Mrs. H. A. L. Fisher, on "The endowment of motherhood," treated in its historical and scientific aspects.

Guy's HOSPITAL MEDICAL SCHOOL.

The following scholarships have been awarded:

Open Scholarship in Arts: W. S. Baxter, J. W. Crow, equal £50 each.

Scholarships for University Students: War Memorial Scholarship, D. Lurie, B.A. Oxon., £80; Open Scholarship, W. D. B. Read, B.A. Oxon., £100.

Scholarships in Junior Science: Confined Scholarship, E. T. Conybeare, £100.

Open Scholarship: R. E. Fossey, E. M. Sharples, equal £50 each.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

*Calendar for 1923-24.*

THE current Calendar of the Royal College of Surgeons has been issued this week; it includes, as usual, the report of the proceedings of Council, together with lists of officers, fellows, members, and diplomates, and the customary official information. In the period under review 49 diplomas of fellowship were issued, including one to a medical woman; 621 membership diplomas were issued, including 137 to women; the licence in dental surgery was issued to 238 persons, including 10 to women. The following are the numbers of diplomas granted during the year jointly with the Royal College of Physicians: Public Health, 66; Tropical Medicine and Hygiene, 39; Ophthalmic Medicine and Surgery, 24; Psychological Medicine, 21. The recipients of the K.C.B., K.C.M.G., late Medical Director-General R.N., and Mr. J. Howard Mummery, C.B.E. (members of twenty years standing) were admitted to the fellowship without examination. The subject of the Jacksonian prize essay for the year 1924 is "The Pathology, Diagnosis and Treatment of Oesophageal Obstruction." Dr. K. N. G. Bailey has been appointed the second Streafild scholar; his research will be carried out at St. Bartholomew's Hospital.

Amended regulations for the licence in dental surgery have been drawn up by the Board of Examiners in Dental Surgery and approved by the Council, these changes being rendered necessary by the alterations in the regulations for the diplomas of M.R.C.S. and L.R.C.P. Regulations for the issue of a diploma in laryngology and otology, in association with the Royal College of Physicians, have been drawn up and are now available for intending candidates. Examinations for the diploma will be held in December, 1923, and June, 1924. The regulations for the D.P.H. have been revised so as to bring them into conformity with the new regulations and rules issued by the General Medical Council; they will come into force on January 1st, 1924.

The financial report states that the income of the College, exclusive of income from Trust Funds, amounted to £42,967, or £3,152 more than in the previous year. The total expenditure in respect of revenue amounted to £38,090, or £4,838 more than in the previous year. The balance of the revenue account amounted to £4,877. In the year just completed more than £3,700 was expended out of revenue on structural and other alterations in the nature of capital expenditure. The Conservator's report states that the most noteworthy event concerning the history of the museum is the completion of the series illustrating the principles of pathology—the great series now exhibited on special stands on the floor of Room III. The Librarian in his report records that the *Lives of the Fellows* has now been carefully indexed, and the process has brought to light a considerable number of references of interest to medical historians at large, but especially to those in search of information as to the history of operative methods, views on disease, and hygiene. The valuable collection of letters relating to College affairs and medical politics during the last eighty years has now been catalogued and put in order.

## The Services.

On October 1st Surgeon Rear-Admiral Joseph Chambers, O.B., C.M.G., took over the appointment of Director-General of the Medical Department of the Navy, in succession to Surgeon Vice-Admiral Sir Robert Hill, K.C.B., K.C.M.G., C.V.O.

### THE BLANE MEDAL.

The gold medal founded by Sir Gilbert Blane, Bt., has been awarded by the Director-General of the Medical Department of the navy and the Presidents of the Royal College of Physicians and the Royal College of Surgeons to Surgeon Lieutenant-Commander Julian L. Priston, M.B., M.R.C.P., D.P.H., R.N., who obtained a first-class certificate at the examination held in February last for promotion to the rank of Surgeon Commander.

### DEATHS IN THE SERVICES.

Lieut.-Colonel de Vere Condon, Indian Medical Service (ret.), died at Waltham Abbey on September 13th, from illness contracted on active service in Persia, aged 49. He was born on April 13th, 1874, the son of the late Major E. H. Condon, and educated at Trinity College, Dublin, where he graduated B.A. in 1895, M.B., B.Ch., and B.A.O. in 1897, and M.D. in 1906. He took the diploma of the London School of Tropical Medicine in 1912; and the D.T.M. and H. at Cambridge in 1913. He entered the I.M.S. as surgeon lieutenant on January 28th, 1898, attained the rank of

(With Special Plate.)

SYDNEY SMITH, M.D. Edin., D.P.H.,

DR. MOHAMMED EMARA,  
ASSISTANT MEDICO-LEGAL EXPERT.

The following case is of considerable medico-legal interest:

An Egyptian, aged about 40, when admitted, was said to have been struck on the head with a stick during a quarrel eleven years earlier. He was rendered unconscious and removed to hospital, where he remained for one month and was discharged cured without paralysis or other disability. For eleven years he worked as a labourer without having the slightest trouble.

On May 15th, 1927, while sitting with some friends he suddenly became unable to speak and felt numbness and heaviness in his right arm and leg. There had been no quarrel, no excitement, no undue exertion. On May 16th he was taken to hospital. He was then semi-conscious, could understand a few words, and responded by indistinct syllables to all questions. There was no squint, no nystagmus, no conjugate deviation. Right arm and leg motionless, muscles not atrophied, no tremors or twitching; pupils normal.

*Superficial Reflexes.*—On the right side the plantar, abdominal, cremasteric, and corneal superficial reflexes are all absent. On the left side the plantar is flexor type, corneal and abdominal present.

Normal. On the left side all are normal. There are no deformities. Blood pressure: systolic, 160; diastolic, 10; pulse 72, full. Diagnosed right hemiparesis with aphasia and an old parietal fracture on the left side noted. The patient remained in hospital for operation, when he died. There were days and was prepared for operation, when he died. There were no signs of abscess or other septic condition. The temperature was between 97° and 99° C. throughout. On both sides were found

[illegible]

and spinal fluid was a roughly circular depression 4.2 cm. in diameter composed of the depressed fragments and showing features which could not be seen externally; there was no calcification. All the edges were smooth and no signs of separation could be observed. (Figs. 1 and 2.) The dura mater was not thickened nor were there any special adhesions. The brain was congested and oedematous and there was a depressed area in the cortex opposite the fracture. The cerebro-spinal fluid was increased in amount. The cortex of the brain appeared normal. Residual brownish material was found in the ventricle, the cavity of which was larger than the right. The optic chiasmata and candidate nucleus appeared very soft and broke up on the slightest touch. The other viscera, including the kidneys, appeared normal; there was no abnormality to be observed. There was no middle ear disease.

The brain was submitted for microscopical examination to the Pathology Department, and Dr. Stewart found, in sections from the softened area, foci of sepsis with areas of interstitial haemorrhage and necrosis, and very slight thickening of the blood vessels.

This case appears to be of considerable interest from many points of view—namely, the rapid and apparently complete recovery and subsequent freedom from symptoms with a considerable area of bone depressing the cerebral cortex over the motor area; the rapid onset of cerebral softening without premonitory signs or appreciable paresis; the extraordinary period intervening between the injury

Two young babies are alive and well. The other died about four days after birth. The mother says she was not able to nurse the child and that she had to give it milk. She says she was not able to nurse the child and that she had to give it milk. She says she was not able to nurse the child and that she had to give it milk.

*Present Unlucky*—She first walked at 13 months, and her present difficulty seems to have dated from about her fifth year, when she started school. She has progressively become more and more nervous. She has been normally healthy, but has lately had four years she has become more and more nervous. She has had malfunctions of sight and hearing and a continual fear of being murdered. She is inclined to repeat the same sentence over and over and is fast becoming more and more mentally backward. The rash was first noticed when quite young, perhaps at 5 or 6 years of age; certainly it has been present ever since 1915. At every spring of her hands, feet, face, and neck becomes red and peeling and at times large blisters appear on them. The rash remained all summer. During the period the rash is present all the child's symptoms are aggravated.

[illegible][illegible][illegible]

*Comment.* In both these cases the rash and affection of the nervous system appear to be typical. Apart from the fact that at some period prior to the onset of symptoms both children were fed on large quantities of "cornflour," there is nothing in the history which would fit in with the various theories of the causation of pellagra. In Case II, at all events, the diet seemed to have contained a sufficiency of protein of high biological value.

These children had both resided all their lives in England and it is probable that the disease is commoner in this country than is at present realized, many cases remaining undiagnosed.

## Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitology Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westrand, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, Medisecra Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### INCOME TAX.

"M. R." submits the following query: A, B, and C had equal shares in a practice; A retired, selling his one-third share to B and C, who sell a one-sixth share in the practice to D. What proportion of A's expenses should D be allowed?

\* \* The question does not really arise. For the year following the change B, C, and D are liable to be assessed on the average profits of the previous three years, taking A's actual expenses into account for each of those years. D will, of course, be liable in respect of one-sixth share of that amount, and B and C in respect of five-twelfths each. When the profits are being calculated for the year during which D was a partner his actual expenses should, of course, be taken and not estimated by reference to A's. For instance, for the second income tax year after the change in the practice B, C, and D will be jointly liable on an assessment calculated on an average of three years, two of which will be affected by A's actual expenses and one year by D's actual expenses.

"M. D." has been refused deductions for (a) the annual subscription to a local medical society, and (b) his subscription to the International Radiological Conference and the cost of his attendance thereat.

\* \* (a) "M. D." can deduct a proportion of his subscription, determined by the ratio of the total subscriptions to the society to the society's expenditure on furthering the interests of its members. (b) If the expenditure was for the purpose of extending his own knowledge—or that of the world generally—it cannot be deducted as an expense of earning his income; it is in some respects capital expenditure analogous to the cost of improving the professional equipment.

#### "ONLY ONE LUNG"?

"E. K." would like to know if it is really true that Grace, the famous cricketer, had from his childhood only one lung. In a book, *The Best I Remember*, 1922, by Arthur Porritt (Cassell and Co., Ltd.), it is stated that Grace affirmed "that he had only one lung, and had, in fact, had only one lung since his childhood."

### LETTERS, NOTES, ETC.

#### DIABETES AND INSULIN: CORRECTION.

SIR THOMAS HORDER asks us to correct a slip in the report of his presidential remarks introducing the discussion on insulin in the Section of Medicine. On page 445 of the JOURNAL of September 15th, thirteen lines from the end of the page, the words "If I were asked . . . modern conception of diabetes," should read "modern conception of diet."

#### CONGENITAL DEFORMITY.

DR. THOS. CARRUTHERS (Kilbarchan, Renfrewshire) writes: Dr. Walker (September 22nd, p. 546) has only to refer to Gould and Pyle's *Anomalies and Curiosities of Medicine* (Rebman, W. B.

Saunders, 1897), Chap. IV, "Minor Terata," to find all the information he desires. My copy was picked up second-hand many years ago, and the book is doubtless out of print, but I shall be glad to put it at Dr. Walker's disposal for reference. The book is a wonderful collection of oddities in medicine and surgery from about the days of Adam, and is profusely illustrated. Reference to it is necessary before deciding that anything extraordinary is an extraordinary thing.

DR. HENRY H. HAWARD (Northwich) writes: When a medical student at St. Thomas's Hospital in July, 1892, I delivered a poor woman, in a loft over a stable off Kennington Lane, of a female child having little or no vestiges of arms or legs, apparently precisely similar to that recorded in your issue of September 22nd by Dr. John Walker of Paisley. The child attempted to breathe, but artificial respiration was practically impossible, and it died after a few minutes. The cord was short and absolutely untwisted. I remember well how the presentation puzzled me until the vulva was exposed, and how much difficulty there was in delivering the head. There was practically no furniture in the room and not even a basin or a cup. There were the remains of a bed but no bedclothes. The poor woman was impoverished and glad to accept 5s. and allow me to take the body away, and I took it to the hospital museum, where Professor Shattock dissected it and set it up as a specimen. It is figured in Treves's *System of Surgery*, 1835 edition, vol. ii, p. 87.

#### HERPES AND VARICELLA.

DR. C. H. SEDGWICK (Weedon) writes: The connexion between herpes and varicella is well brought out in the following instance: A few days ago, whilst on a visit to some friends, I learned that my hostess, the mother of three young children, had just recovered from a moderately severe attack of herpes affecting the right arm and shoulder. I remarked to her that now possibly her children would develop chicken-pox. To-day, six days afterwards, I hear this has actually happened, her eldest child, 4 years of age, having developed the disease. I understand there is no other known source of infection.

#### DISLOCATION OF SEMILUNAR CARTILAGE: NATURE'S CURE.

DR. CHARLES J. HILL AITKEN (Kilnhurst, near Rotherham) writes: Some ten years ago a middle-aged man took part in a game of hockey "to fill a gap," and, unused to the exercise, damaged his knee. The diagnosis was undoubtedly dislocation of the left internal semilunar cartilage. He was unable to lie up. Two years ago the cartilage would slip out under very slight provocation. Luckily there never was synovitis, and if the cartilage slipped out of place easily it would as easily slip back into position. The patient then got work that involved much walking and bicycling on country roads. Six months later it suddenly struck him, his cartilage had ceased to bother him. The other day he told me that for eighteen months his cartilage had never once slipped out. Presumably the exercise of walking and cycling had strengthened the thigh muscles that they were able to keep the cartilage in its place, although it is not likely that it is fixed.

#### PULMONARY TUBERCULOSIS IN A YOUNG CHILD.

DR. W. BAYLY PEACOCK (London) writes: A girl of 4½ years was brought to me with the complaint that she had a heavy cold which she "did not seem to throw off" and that she was losing weight. On examination she appeared thin and anaemic but quite cheerful. The temperature was normal. There was no undue prominence of the superficial veins on the thorax. On percussion there was a large area of dullness on the right side over the position of the lower lobe of the lung. On auscultation there were signs of a bronchitic type over the left lung and also to some extent over the right one, but over the area dull on percussion was marked tubular breathing and numerous crepitations. I found the child had a cough, but no sweating at night, nor was there any history of her being in contact with any tuberculous person. I gave the mother a sterile bottle and she was able to persuade the child to spit into it. The borough tuberculosis officer, Dr. MacDonald, kindly examined this and found numerous tubercle bacilli present. He afterwards examined the child and agreed with me that it was undoubtedly a case of tuberculosis of the lungs of an adult type. From the literature I have at hand on the subject it would appear to be rather an unusual type for so young a child.

#### UNUSUAL POSITION OF CHILD DURING DELIVERY.

"COUNTRY G. P." writes: Your correspondent Dr. W. F. Moore (September 29th, p. 565) has not mentioned the condition of the mother and child after the prolonged labour with the head in an unusual position.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 33, 35, and 37 of our advertisements columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 34, 35, and 36. A short summary of vacant posts notified in the advertisements columns appears in the Supplement at page 159.

The slightest markings or "graininess" on a screen make it quite unsuitable for kidney work.

The mid-ureters are next examined, or the whole tract may be done in two sections. Here again a rapid exposure should be made, for although the ureters, or at any rate the greater part of them, do not move with respiration, a shadow, such as a calcified mesenteric gland would cast with respiratory movements, would be blurred. The blurring in itself would be of some significance, but it is better to get a sharp outline rather than a blurred one. The tube should be parallel to the film in this section of the tract.

The bladder region is next examined, and it is of vital importance that the tube is well tilted so that, with the patient supine, the opening of the extension tube points well into the opening of the pelvis. If this is not done small shadows at the base of the bladder and in the prostate or prostatic urethra will certainly be obscured by the overlapping shadow of the pubic arch. If the patient is examined from below and lying prone, it is necessary to "open" the pelvis by putting an air cushion under his thighs. If the patient is screened in this position the clearer view is very striking as compared with that taken when he is lying flat.

This, then, is probably the technique most frequently adopted in routine cases and as a preliminary in the more difficult ones. An improvement of much value is the use of the Röntgen-Bucky diaphragm, for the results obtained are of much finer quality and of correspondingly greater diagnostic value. If a shadow is found which is rather indefinite, or which suggests that it might be due to intestinal contents, it is usual to repeat the examination in a few days' time after further purgation. If the shadow was due to feces it is most improbable that it will still be present in the same position on the second examination. It is a very sound procedure to confirm abnormal shadows in the urinary tract unless there seems no doubt at all about their interpretation.

Radioscopy of the urinary tract is of considerable value, especially the larger kidney and bladder ones, can be seen, but perhaps the chief value of screen work is in determining the relative movement of a supposed stone shadow to that of the kidney and its direction of movement with respiration. This is really the same as the method of taking two films, one on deep inspiration and the other on deep expiration, and comparing the relation of a shadow to one of the poles of the kidney on the two films. Radioscopy is also of great value in the diagnosis of a movable kidney. Another use is in the examination of an exposed kidney at the time of operation. Though not often made use of in this country it is of value in certain cases.

We may now pass to the more special technical methods which, although they may not be employed in every case, are nevertheless in everyday use in selected cases. They are specially indicated when it is required to know the exact relation of a shadow to some part of the urinary tract or the shape and size of the kidney itself.

Later views of the kidney and ureter are taken, with the patient lying preferably on his back and with the tube at his side. The position of the kidney lies superimposed on the bodies of the first, second, and upper part of the third lumbar vertebrae, but one does not see its actual outline. It cannot be too strongly urged that a lateral view is of the utmost value in the differential diagnosis of shadows in the renal area, especially on the right side. In cases of movable kidney, if the patient is lying on his side the kidney may fall forwards, and it is for this reason that the supine position is recommended as more accurate. Stereoscopic views are also made use of, but the writer thinks that they are not of as much value as antero-posterior radiograms combined with lateral.

Peritoneal injection of oxygen or CO<sub>2</sub> consists of injecting the peritoneal fat with 200 to 600 c.cm. of oxygen or CO<sub>2</sub>, through the loin by a lumbar puncture needle. In demonstrating kidney stones which it would be exceedingly difficult or even impossible to show without its aid, it is also of much help in showing up renal tumours.

The contraindications for this procedure are dense adhesions around the kidney such as follow an operation. It is a comparatively painless method and is safe, though cases have occurred in which the kidney tissue has been punctured.

Pneumoperitoneum is a method by which oxygen or air is injected through a hollow needle inserted through the anterior abdominal wall into the peritoneal cavity under local anaesthesia. By its means a very well defined shadow of the kidneys is obtained, and it is of special value in the diagnosis of renal tumours. Care should be taken not to mistake the shadow of the spleen for that of the left kidney. With this technique the lateral view is of special value. The patient is put in the prone position with his chest and thighs so that the stomach, intestines, and other organs with mesenteric attachment fall forwards, and the tube is at the side of the couch. This view shows clearly the retroperitoneal structures, and, owing to the falling forwards of the intestines, etc., creates a clear retroperitoneal space. This is of great value in the differential diagnosis between masses arising retroperitoneally, such as a kidney growth or a psoas abscess, which encroaches forwards on the retroperitoneal space, and other masses arising from the abdominal organs, which fall forwards and so leave the retroperitoneal and prevertebral spaces clear.

The procedure is unfortunately accompanied by a certain amount of discomfort and is not without danger. I have had one fatal case, due to the presence of minute perforations on one side of the diaphragm which caused a pneumothorax, collapse, and death within a few hours.

Colon inflation is a much simpler method than the two foregoing, and consists simply of pumping in air through a rectal tube. It should be done under the control of the screen, for there seems to be an optimum effect which can only be determined in this way. It is quite painless and free from danger, and is a method worth bearing in mind when there is difficulty in showing up the kidneys to get confusing shadows from the sacculations of the colon.

An opaque ureteral bougie, passed by means of the cystoscope, is of special value in determining the relation between shadows in the neighbourhood of the ureter and the ureter. When *in situ*, films should be taken in two positions at different angles, and if the shadow is seen in the same close proximity to the bougie in the two films one is justified in assuming the shadow to be a stone in the ureter. In exceptional cases, however, such as hydronephrosis, there may be a space between the shadow and the bougie and yet the condition be one of ureteric stone.

Pyelography is one of the most valuable aids we have in urinary examination, but the cases in which it is done should be selected. It consists of injecting very carefully an opaque solution into the pelvis of the kidney through a ureteral catheter by a syringe or by gravity. At the present time the solution most in favour is a 10 to 20 per cent. solution of sodium iodide or bromide. Collargol, previously much in vogue, should not be used on account of its irritating properties. It must be admitted, however, that the ideal solution for this work is yet to be found. It is advisable that only one side should be done at a time, and it is safer not to use compression. As its name implies, its special value is in outlining the renal pelvis and showing whether it is dilated or distorted. It also shows the relation of the kidney pelvis to the shadow of a stone already found in the kidney region.

Later pyelography is frequently used; here the pelvis is seen as an elongated shadow over the body of the

60 infants in the first group developed measles. As many as 35 of these 60 infants died. Of the infants given the serum of convalescents 59.7 per cent. failed to develop the disease; of the infants given the serum of adults only 36, or 47 per cent., developed measles. There were only 4 deaths among the infants given the serum of convalescents and only 5 deaths among the infants given the serum of adults.

#### 258. Hypochlorhydria and Dyspepsia.

P. SAVY and P. DUFOUR (*Journ. de Méd. de Lyon*, July 20th, 1923, p. 425) give details of six cases (four men and two women) in which free HCl was entirely absent on admission. The total acidity was very low, and in only one case (male, aged 55) free HCl was found after two months' dietetic and antisyphilitic treatment (this patient had a ++ Wassermann reaction). Another patient (female, aged 45) was cured by subtotal hysterectomy and ovariectomy for a large fibroma. The majority of the male patients were careless in eating; two were alcoholic and took coffee and smoked to excess. The authors found no evidence of gastroparesis, and in only one case (vi—the patient cured by hysterectomy) was any pyloric spasm seen. They conclude that certain dyspepsias exhibit a complete absence of HCl, which in all their cases was associated with rapid evacuation of the stomach and delayed pain—symptoms usually considered indicative of hyperchlorhydria. Absence of HCl, say the authors, is found in normal subjects who make no complaint of dyspepsia. They suggest that "the other secretions of the digestive organs" may supplement and correct the deficient secretion of the gastric mucosa.

### Surgery.

#### 257. The Diagnosis of Surgical Lesions in the Right Iliac Region.

A. B. COOKE (*Journ. Amer. Med. Assoc.*, August 25th, 1923, p. 627) says that most intra-abdominal operations are in reality exploratory. After every diagnostic resource has been exhausted it happens with disconcerting frequency that conditions are encountered at operation of a different and far more serious character than was anticipated. This is especially true in lesions of the right iliac fossa, in which the appendix so completely dominates the diagnostic picture. As a matter of fact, fully 90 per cent. of the surgical lesions of this region do originate in the appendix. But the remainder constitute too large and too important a clinical group to be ignored or lightly considered. Cooke cites four cases which, when first seen, presented every appearance of a typical acute attack of appendicitis, and delay for more prolonged consideration seemed both unwise and unwarranted. In the light of the operative findings it was quite evident that accurate differential diagnosis would not have been possible even had time for investigation been unlimited. The actual conditions found were as follows: (1) An inflammatory mass in the ileum, with volvulus; (2) necrosis of the caecum and base of the appendix; (3) a short ascending colon, freely mobile caecum, and highly inflamed appendix in contact with the gall bladder; (4) a greatly thickened caecum with a distinct tumour as large as a medium-sized fist, occupying the whole of the space between the origin of the appendix and the ileo-caecal junction, the appendix being in no way involved; the tumour proved to be a diverticulum of the caecum containing a firm, round faecolith approximately three-quarters of an inch in diameter, in a mucus-lined pocket more than an inch from the lumen of the intestine. These cases indicate the diagnostic uncertainties and emphasize the operative difficulties and complications that may be associated with the surgery of appendicitis. The author goes on to deprecate the promiscuous operating for appendicitis which he suggests is prevalent in America, and demands a minimum standard of fitness for the practitioner who undertakes major surgery.

#### 258. Dupuytren's Contraction.

A. Q. VAN BRAAM HOUCKGEEST (*Nederl. Tijdschr. v. Geneesk.*, September 8th, 1923, p. 1032) states that Dupuytren's contraction has hitherto been regarded chiefly as a surgical affection, and has therefore received more attention in surgical than in neurological textbooks. He is, however, inclined to agree with Neutra in the view that there is a connexion between Dupuytren's contraction and the central nervous system. He considers it improbable that injuries caused by manual labour play an important part in its production, as precisely the same phenomenon occurs in the feet. Moreover, the rarity of the affection in relation to the enormous number of persons engaged in manual labour and the occurrence of inherited cases are against manual labour or injury being a causal factor. It is also note-

worthy that operative treatment is only rarely successful. Houckgeest has recently seen three cases in one family—namely, the father, aged 62, and two sons, aged 29 and 33 respectively. The third child, a girl, was unaffected. The father showed cerebral symptoms in the form of a tendency to suicide and disturbance of speech. He first developed Dupuytren's contraction at the age of 47, and the two sons affected, in the elder son the right hand only, and in the younger the left hand only. Both the sons were of a nervous disposition; the elder had had hysterical amblyopia and the younger son continuous tremors. Neither of them was engaged in manual labour. Houckgeest recommends that in autopsies on cases of Dupuytren's contraction a systematic examination should be made of the central nervous system.

#### 259. Gangrenous Balanitis.

J. B. CROSS and R. B. ZEVALKINK (*Urol. and Cut. Rev.*, September, 1923, p. 561) define gangrenous balanitis, which is sometimes known as "the fourth venereal disease," as a specific and infectious venereal disease due to symbiosis of a vibrio and a spirochaete, with local and constitutional symptoms varying with the severity of the infection. The condition was first described in 1891 by Batille and Berald, who reported 120 cases. The disease, which is comparatively uncommon, rarely occurs except in those with long foreskins. Two types of the disease are described—namely, the ulcerative and the gangrenous, the latter being merely an advanced stage of the former. The ulcerative type is characterized by the presence of one or more ulcers varying in size from a pin's head to a pea, which in most cases become deep and gangrenous. They differ from the large ragged ulcers of chancre and from syphilitic chancres in not being indurated and being more painful. A thin characteristic muddy pus is present, which has a foul permeating odour. Gangrene quickly sets in and the glans becomes converted into a friable, slimy, soft, black mass. The foreskin is thickened, red, and oedematous, and cannot always be retracted. The inguinal lymph glands are not usually involved. The patient presents evidence of a general septicæmia with a temperature varying from 100° to 104° F. The disease must be differentiated from chancreoid syphilis, gonorrhoea, herpes preputialis, and simple balanitis. The author's treatment is as follows: If the foreskin cannot be retracted easily a dorsal slit is performed under local anaesthesia and the infected area is thoroughly cleaned with hydrogen peroxide. The penis is then immersed for fifteen minutes in a hot solution of potassium permanganate 1 in 3,000, after which a loose bandage soaked in the same solution is applied. The bandage is kept moist by application of a fresh solution every half-hour. Every four hours it is removed, the parts are again cleansed with peroxide, and the procedure repeated. After three or four days' treatment a line of demarcation appears and the necrotic area can easily be removed. The use of oxidizing agents should be continued until all evidence of active necrosis has subsided.

#### 260. Treatment of Inequality of Length in the Lower Limbs.

As N. D. ROYLE (*Med. Journ. of Australia*, June 30th, 1923, p. 716) points out, there is probably no more conspicuous disability than that caused by inequality in length of the lower limbs. This deformity is particularly burdensome to girls, and relief is usually sought by massage or attempts to equalize the length by alterations in the footwear. It is far better to equalize the length of the lower limb by some operation on the bony skeleton. It is easy to remove a section of bone from the lower limb, and this he has done in five cases. A piece of bone may be removed from the femur, this being approached from the lateral aspect. The length to be removed is marked off and the bone drilled in three places; it is then divided between the drill holes with a sharp osteotome. This leaves surfaces which interlock easily. An intramedullary splint may also be made from the excised piece of bone. The limb is then fixed in plaster of Paris for eight weeks and a Thomas's knee-splint worn until union is satisfactory. The muscles and skin presented no difficulty in the shortened limb.

#### 261. Syphilis of the Stomach.

W. A. BRAMS and K. A. MEYER (*Surg., Gyn., and Obst.*, August, 1923, p. 127) assert that acquired syphilis of the stomach anatomically proved may be considered a rare disease, judged by the number of reported cases. Only 14 recorded cases could be discovered which were definitely proven. Resected specimens showed the following characteristic changes: thickened submucosa, shallow, multiple and irregular ulcers, and the presence of visible military gummata. The entire pyloric portion of the stomach was thickened and infiltrated. The clinical evidence depended

inhydrosis, then downwards and inwards towards the base of the bladder. When a stone obstructs the ureter its position may become greatly altered. Stones in the ureter are usually of a small size, of an elongated oval shape, and lying in the line of the ureter. If the ureter is much dilated the stone or stones may be very much larger. The larger the stone, the more the ureter tends to run parallel to the transverse processes. Stones may travel forwards and backwards from the renal pelvis to the lower ureter. For this reason a film should be taken on the day of operation if the x-ray examination was made some days previously. A frequent site for a ureteric stone is at the entrance into the bladder, where it seems to be held up before passing through the orifice.

The following conditions may be mistaken for ureteric stones:

- (a) Calculi abdominal glands. (See under the kidney area.)
- (b) Accessory epiphysis for the tip of the transverse process.
- (c) Concretion in the appendix.
- (d) Calcification of the iliac artery.
- (e) Calcification of the sacro-sciatic ligament.
- (f) Pheboliths.

Calculated abdominal glands. (See under the kidney area.)

An accessory epiphysis for the tip of the transverse process will lie in the line of the ureter, but its base, fitting exactly to the rest of the transverse process, should make one suspicious. A small ureteric stone may, however, be completely superimposed on the shadow of a normal transverse process.

A concretion in the appendix or the stump of an excised appendix treated with iodiform paste may lie in the line of the right ureter and present a shadow suggestive of stone.

An opaque bougie with films taken at two angles should help to differentiate.

Calcification of the iliac artery may occur in the line of the lower part of the ureter. The lime deposit is wavy in appearance and should not be mistaken for stone.

Calcification of the sacro-sciatic ligaments is streaky in appearance, and not like that of stone.

Pheboliths are often liable to be mistaken for ureteric stones, and in some cases it is difficult to differentiate. They may occur, as age advances, without any pathological significance, and are due to the formation of small calcareous nodules in the pelvic veins. They show as small rounded shadows along the sides and lower parts of the pelvis. At times they are oval, and are then more likely to be confused with stone. Frequently one or more are seen near the ischial spine. They are distinguished by being usually external to the line of the ureter, are generally rounded in shape, and usually multiple. An opaque bougie is often necessary to differentiate them, with two views at different angles. Even this is not infallible and it may be necessary to take two films—one with a soft pliable opaque bougie which adapts itself to the pelvic curve of the ureter, and the other with a rigid metallic dilator which straightens it out.

### III. Bladder Area.

The position of the bladder is well known, but it should be clearly realized that its base is below the level of the pubic arch, so that a true antero-posterior view will not give a clear view of its lowest part. As already stated, the tube or the patient should be well tilted to avoid the pubic arch. Vesical calculi are usually larger than kidney or ureteric ones, are generally rounded or oval in shape, and may show different densities owing to the deposition of layers of different chemical composition. At times a typical vesical stone or group of stones may be encountered in an abnormal position, and it is then well to consider if they are in a diverticulum of the bladder. In the diagnosis of a diverticulum opaque solutions are used, with films taken at different angles. The patient then voids, and another film taken will show the amount of retention. Diverticula are of considerable etiological importance in the formation of stone. The diagnosis of stone in the bladder is usually easier than in renal or ureteric stones owing to their size and relative immobility.

of the organ in the pelvis. The following conditions may, however, have to be differentiated:

- (a) Prostatic calculus.
- (b) Faecal masses in the rectum.
- (c) Calculi abroad.
- (d) Pheboliths.
- (e) Dermoid cyst containing opaque material.
- (f) Calcification of seminal vesicles.
- (g) Foreign bodies.

Prostatic calculi are much commoner than is usually supposed, and it is thought that many have been overlooked by the overlapping of the pubic shadow. They are seen lying very low in the pelvis, and may be single or multiple. If the latter, they usually show a radiating appearance from the mid-line. They are usually not so large nor so dense as vesical calculi.

Faecal masses in the rectum are not so dense as stone, and should not be mistaken for them. They are due to inefficient clearing out of the bowel.

Calculated fibroids show as large, dense, irregular masses, but should not be mistaken for stone in the bladder. Pheboliths are usually external to the bladder, and from their small rounded shape and from usually being multiple they should not be confused with stone.

A dermoid cyst containing opaque material, such as a tooth, may be mistaken for a stone.

Calcification of the seminal vesicles, due to old age or tuberculosis, may cast a shadow which has been confused with stone in the bladder.

Foreign bodies in the bladder, especially in the female, have been mistaken for calculi, or phosphatic deposits on them may have turned them—from a practical point of view—into stones.

### IV. Urethral Area.

For the detection of urethral stones it is of even more importance than in bladder work that the tube should be well tilted to avoid the shadow of the pubic arch. These stones may either have formed higher up and become lodged in the urethra, or they may have formed in the urethra itself or in some cavity communicating with it. The most common site is in the prostatic urethra, and these are frequently due to prostatic calculi forming pockets in the gland which tend to establish communication with the urethra. A urethral stone may, however, be found in any part of the urethra, and is then usually due to a stricture impeding its downward passage; not only is it held up but its size may be increased by phosphatic deposit from the unhealthy urine.

The investigation of conditions of the urinary tract other than stone demands careful and elaborate technique, for here one has to depend largely on the outlining of the soft organs. Probably not so much information regarding the shape and size of the kidneys is furnished as might be in ordinary routine examination. If the outlines of the kidneys are seen as they should be, then the report should include some information as to their size and shape. Their position as seen on films is not so trustworthy, because if compression has been used it is more than likely that this has had some effect and a movable kidney may be pushed up into its normal position. With films of good quality it should not be very difficult, with experience, to say whether a kidney appears enlarged and whether its shape is normal. It is possible, in conjunction with the clinical notes, to make a fairly accurate diagnosis of pyonephrosis simply by the routine method, especially when the shadow shows increased density from inspissated pus with deposition of lime salts.

For more accurate diagnosis of these conditions further technical methods are required, such as pneumoperitoneum or peritoneal inflation, to show up the kidney outline, or pyelography to show the size and shape of the pelvis and calyces of the kidney. The normal outline of the injected pelvis is well enough known not to require description, and when it becomes distended it presents a more globular shape and the calyces become more elongated. The pyelogram is undoubtedly one of our greatest aids in making the diagnosis of pyonephrosis and in determining

The end-results were excellent, 86 per cent. being well and only 6.5 per cent. complaining of even slight pelvic discomfort, this being recorded in most cases to the bladder. The author advances a new theory regarding the bleeding which occurs with fibroids; he states that it is not due so much to lack of tone of the uterine muscle as to a hypertonicity around the tumour which retards the return flow of blood, and on that account small veins rupture and cause bleeding. Pain is stated to be of rare occurrence, and if present the abdomen should be explored thoroughly for another lesion. It is in fibroids situated in the lower part of the uterus, which is supplied by the hypogastric plexus through the inferior hypogastric nerve, that pain is most common, whereas those occurring in the fundus, which is supplied by the ovarian plexus, give rise to no pain. The author advises that operation should not be done if the patient comes under any of the following categories: (1) If the fibroid occurs during the child-bearing period, and the patient being desirous of a child suffers little from the disease. (2) If the fibroid occurs in a pregnant uterus, but is causing no or little discomfort. (3) When the patient suffers from some dangerous intercurrent disease—for example, diabetes, chronic Bright's disease, etc. (4) When fibroids are present in old women, but have ceased growing and produce no symptoms. The author concludes by stating that myomectomy is the best operation for patients under 35 when the fibroids are single or few in number, and that it is no more precarious an operation than hysterectomy. In performing supravaginal hysterectomy the cervical stump is coned out and the round ligaments are implanted into the stump.

**Vagitus Uterinus.**

B. NYSTRÖM (*Finska Läkaresällskapet's Handlingar*, July-August, 1923, p. 469) notes that the prognosis for the infant who cries aloud before birth is good, only 8 out of the 58 infants reported to have done so being born dead (Stoeckel's summary in 1923). Many of the infants born alive were said to have cried hours and even days before they were born. The author contributes the following new case. A pluripara, aged 27, showed a head presentation, the membranes being intact, and the pulsating umbilical cord being palpable between the membranes and the foetal head. As the cord could not be replaced, and there were signs of its being compressed during labour pains, and as the os was almost fully dilated, the membranes were ruptured under other anaesthesia, and the cord was simultaneously thrust back into the uterus. While pressure was being exerted on the head and attempts were being made to displace it and secure one of the legs, the infant cried aloud repeatedly, the cries being audible to all present. Version was rendered difficult by the size of the infant, and it was not till the head had been displaced up into the fundus of the uterus that the crying ceased. Labour was completed immediately after version had been performed, a well developed male infant, weighing 4,190 grams, being born. The slight asphyxia observed at birth passed off almost at once, and the mother and infant were discharged from hospital in good health.

**267. Treatment of Pyelonephritis in Pregnancy.**

MARTIN (*Journ. d'Urologie*, June, 1: 23, p. 445), in a paper on the indications for treatment of the more serious types of pyelonephritis of pregnancy, states that while death is very rarely the termination of this condition, yet it has been reported, and he considers that the current belief that this is a benign condition is largely because the more grave cases have not been published. He emphasizes the importance of having a more precise mode of procedure for dealing with these cases. As regards artificial termination of pregnancy he quotes 10 cases, in 7 of which the results were excellent and immediate. Speaking of nephrostomy, 9 cases of which were noted, including one of his own, abortion followed in 3, and in 3 a secondary nephrectomy had to be performed, but in the latter the cases were probably not true pyelonephritis of pregnancy but cases of renal disease antedating the pregnancy and aggravated by it. Further, although nephrostomy is not of itself serious, yet it is not without danger, for the possibility of secondary haemorrhage should always be borne in mind. He finds it impossible to give definite indications for nephrostomy on the one hand, and for the artificial termination of pregnancy on the other, but believes that in the light of our present knowledge, if for any reason it is not possible to catheterize the ureters in this condition, it is better to interrupt the pregnancy or perform nephrostomy. He concludes by saying that ignorance of the indications for the last two procedures is a consequence of the lack of clinical evidence available on this subject, in that the graver type of case is seldom reported.

**Pathology.**

268.

**The Fixation of the Kidney.**

A. H. SOUTHAM (*Quart. Journ. of Med.*, July, 1923, p. 283) gives the results of an exhaustive investigation into the question of the fixation of the kidney. The author cut sections of six fetuses and seven adult bodies, examined over forty bodies and made plaster casts of the renal fossae, in addition to analyses of hospital records. He finds that the renal fossae differ in shape in the two sexes; in males they are pear-shaped and narrower below, while in females they are relatively narrow above and broaden out below; the right fossa is usually a little larger than the left. The kidney is enclosed with the suprarenal capsule in a fascial envelope composed of a strong posterior and a thinner anterior layer. This fascial sheath is firmly attached to the diaphragm, vertebrae, and transversalis fascia; above and at the outer side it is closed by the fusion of its anterior and posterior layers; at the inner border the layers come together but do not fuse, while below they can be easily separated. There is thus a potential channel below ready for the kidney to descend into should prolapse of the organ occur. The position of the kidneys in man is such that they are constantly exposed to the action of gravity, which tends to produce their prolapse. The most important factors giving support to the kidneys are the perirenal fascia, the renal pedicle, and the maintenance of intra-abdominal tension. Mobile kidney occurs more frequently among females, owing mainly to the shape of the renal fossa. The determining factor in many cases is a relaxed abdominal wall, and this affects females more than males, owing to the inferior muscular development in women, pregnancy, and the different mode of living in the two sexes, which leads to loss of muscle tone in the female. Displacement of the right kidney is more common, not only on account of the shape of the renal fossa, but on account of the presence of the liver on that side; the left kidney is also more securely supported by neighbouring structures. The paper is illustrated by a number of interesting diagrams and by photographs and microphotographs of specimens. It concludes with a full bibliography.

269.

**The Virulence of the Nervous Centres in Sydenham's Chorea.**

P. HARVIER and J. DECOURT (*C. R. Soc. de Biologie*, July 21st, 1923, p. 468) report the result of some researches which they have conducted on the virulence of the central nervous system in chorea. The brain was removed from a man of 86 years of age, who during the last week of life had manifested incessant choreic movements, generalized, and accompanied by purpura of the trunk and limbs, as well as signs of mitral endocarditis. Microscopical examination revealed only minimal lesions in the cortex and grey centres. Two rabbits were injected intracerebrally and inoculated on the scarified cornea with an emulsion of fragments of the brain tissue. One of the animals developed a very mild keratitis which cleared up in a week; the other showed intense keratitis with conjunctivitis and chemosis, and died on the tenth day. By taking the corneal exudate of this second rabbit it was found possible to transmit a keratitis in series; the first two animals developed keratitis but got well; the third rabbit developed keratitis and died on the twenty-eighth day; the eighth rabbit died on the twenty-first day, and the thirteenth rabbit died on the tenth day. The brains of the animals which succumbed were found to be virulent for normal rabbits. Whether they died after corneal or subdural inoculation, the animals showed the same lesions at autopsy. These consisted in an intense mononuclear meningitis and in subcortical and parenchymatous perivascularitis. Further researches are being conducted to determine the relationship of the virus isolated from this case with that responsible for encephalitis lethargica.

**270. The Leucocyte Count after Blood Transfusion.**

H. L. M. VAN DER HOFF (*Nederl. Tijdschr. v. Geneesk.*, August 11th, 1923, p. 571) states that when a blood examination is made at intervals of a quarter or half an hour during the first eight hours after transfusion of 300 to 500 grams of citrated blood the following results are obtained: (1) The number of leucocytes usually increased during the first few hours. This phenomenon was not constant, as in some patients there was a leucopenia. (2) All the patients showed a distinct increase in the neutrophil polymorphonuclear leucocytes in the first few hours after transfusion. (3) This increase took place at the expense of the lymphocytes as of all other forms of leucocytes. (4) The change in the number of the phagocyte was insignificant. The same could be said of special cells, such as plasma cells, and Türck's "irritation cells."

The President (Dr. Gilbert Scott) said that the success of x-ray examination of the urinary tract depended, first of all, on proper technique, and, secondly, on accurate interpretation. Interpretation was rendered easier if the technique was correct. He did not think that Dr. Salmon had laid quite enough stress on the importance of attention being paid to minute or apparently unnecessary small technical details. Two of the most important of these details were the preparation of the patient and efficient compression. As to the respective merits of films and screen examination, personally he preferred films, but if one used intensifying screens for kidney work one should be sure that one did not overexpose. It was much better to have a definitely underexposed plate if the intensifying screen was being used for kidney work. All sorts of weird shadows would be found on the plate if there had been slight overexposure. It was important that the plates should be carefully examined in proper lighting. He desired to lay stress on the value of showing the shadow of the renal outline. He did not think that pyelography was used to anything like the extent it should be. Mr. Ogier Ward considered it a laborious and troublesome affair, but personally the speaker was able to do the whole operation in half an hour. It depended, to a certain extent, on the surgeon; the surgeon must co-operate, but if he was expert in passing the catheter without delay the whole thing could be done in half an hour. There was, however, no absolute co-operation. Pyelography was of extreme value, and he did not think the surgeon used it to anything like the extent he should. With regard to the matter of perirenal inflation, he had been rather disappointed. He could not persuade the surgeon to take it up, and he could not do it himself, as he did not think it was for the radiologist actually to place the needle and pump in the air. He thought it ought to be considered as an operation. He had been trying to persuade many surgeons to do it, but they would not; they said that the danger of penetrating the artery was too great. His own view was that, if ordinary precautions were taken, there would be no danger, and it would be of great value in certain cases. He desired to ask Mr. Ogier Ward whether, after using his 20 per cent. of sodium bromide, haematuria had occurred in any of his cases. It had been reported to him that sodium bromide did tend to cause haematuria after it had been used. He agreed with Dr. Rowden that the screen examination was not sufficiently used. Personally he used a screen examination after he had seen a suspicious shadow on the plate. For further investigation screen examination was invaluable. He did not quite agree that every case should be dependent on screen examination only, because he had seen faint shadows on a plate, and on screen examination had absolutely failed to find them. Although he knew exactly where they were, he could not see them. Therefore he had come to the conclusion that while in ordinary work screen examination would certainly be quite reliable, in very fine work shadow, possibly of vital importance in the diagnosis, might easily be overlooked. At the same time, screen examination was of extreme value, and to his mind was not used sufficiently. He thought it was not enough appreciated.

Mr. Ogier Ward, in reply to the President's question, said that he had not come across any case of haematuria in his hospital resulting from the use of 20 per cent. sodium bromide. Dr. Rowden said that his method was to screen first, and then to radiograph in the old-fashioned way.

Dr. R. W. A. SALMOND, who also replied, said that the remarks and criticisms of the President of the Section were very welcome, as Dr. Gilbert Scott was well known to be a past master in this branch of radiology. The speaker, however, did not agree with him that proper compression did not immobilize the kidney, because in earlier days it was possible to demonstrate the sharp outline of the kidney with an exposure too long for the patient to hold his breath and with only compression as a help. With regard to the relative values of ureterography and opaque bougie, he agreed that the former was the more important. He was greatly interested in Dr. Rowden's remarks in advocacy of screen examination with artificial Pneumoperitonium and Perinephritis (Lancet, March 17th, 1921, p. 1057).

Dr. JAMES MONTAGUE (London) said that the whole question of the radiography of the urinary organs depended principally upon the technique employed, and personally he would certainly depend upon films to get an accurate knowledge of the conditions. No eyes could be as sensitive as the x-ray emission. He agreed with Dr. Batten in thinking that one of the greatest developments in urinary work was the method elaborated by Dr. Carelli, of Buenos Aires. A year or two ago he saw Dr. Carelli apply this method in a case at the French Hospital in London. The extraordinary clarity of the picture which was obtained with the perinephritic injection of oxygen or carbonic acid gas was so remarkable that it must mean a great improvement in the present methods of diagnosis. When one could see the suprarenal body quite distinctly and judge as to its condition and as to the presence of extraneous growths and other things of a like character, one could not but think that the method must come very largely into vogue in this and in other countries. Dr. Carelli could apparently make his injections with absolute safety, and had no trouble of any kind whatever. Another valuable improvement lay in the use of the Potter-Bucky diaphragm. An extraordinarily large proportion of the people affected with kidney calculi and disease of the kidney were very stout people, and although he had heard a prominent radiologist say that, with the use of compressive methods, he could squeeze even the stoutest person into a suitable position for this purpose, this was not so readily done in a good many cases, the people objecting very strongly to such compression as that. The Potter-Bucky diaphragm certainly eliminated a number of the disturbing shadows, and with very little compression, furnished a picture of great clarity, which made diagnosis infinitely easier. In the speaker's opinion the whole subject was in a state of flux at present, though it was true that great advances were being made which in the course of time would enable medical men to say with the greatest accuracy to what the condition was due—whether a calculus or disease or some extraneous trouble.

Dr. R. M. BATTEN (Belfast) referred to one class of case in which pyelography was of great value. One came across a good many cases where the symptoms were such that one would expect to find a calculus either in the kidney or in the upper part of the ureter. Clinically the condition seemed very much like that of calculus, and yet nothing could be seen. When, however, a pyelogram was taken a very definite kinking of the upper part of the ureter would be found. On operation those cases were found to have a definitely abnormal renal artery crossing the ureter and compressing it. In two or three cases which had been followed up a division of that abnormal renal artery had completely relieved the symptoms. That was a condition which he did not think could have been shown except by a pyelogram.

Dr. JAMES MONTAGUE (London) said that the whole question of the radiography of the urinary organs depended principally upon the technique employed, and personally he would certainly depend upon films to get an accurate knowledge of the conditions. No eyes could be as sensitive as the x-ray emission. He agreed with Dr. Batten in thinking that one of the greatest developments in urinary work was the method elaborated by Dr. Carelli, of Buenos Aires. A year or two ago he saw Dr. Carelli apply this method in a case at the French Hospital in London. The extraordinary clarity of the picture which was obtained with the perinephritic injection of oxygen or carbonic acid gas was so remarkable that it must mean a great improvement in the present methods of diagnosis. When one could see the suprarenal body quite distinctly and judge as to its condition and as to the presence of extraneous growths and other things of a like character, one could not but think that the method must come very largely into vogue in this and in other countries. Dr. Carelli could apparently make his injections with absolute safety, and had no trouble of any kind whatever. Another valuable improvement lay in the use of the Potter-Bucky diaphragm. An extraordinarily large proportion of the people affected with kidney calculi and disease of the kidney were very stout people, and although he had heard a prominent radiologist say that, with the use of compressive methods, he could squeeze even the stoutest person into a suitable position for this purpose, this was not so readily done in a good many cases, the people objecting very strongly to such compression as that. The Potter-Bucky diaphragm certainly eliminated a number of the disturbing shadows, and with very little compression, furnished a picture of great clarity, which made diagnosis infinitely easier. In the speaker's opinion the whole subject was in a state of flux at present, though it was true that great advances were being made which in the course of time would enable medical men to say with the greatest accuracy to what the condition was due—whether a calculus or disease or some extraneous trouble.

September 8th, 1788, was communicated by our founder, J. C. Lettsom, and is printed in the second volume of the *Memoirs of the Medical Society of London* (1794). The treatment consisted in "temperance in diet, a diminution in the usual quantity and a change in the quality of the food, an increase in exercise, the occasional loss of a few ounces of blood, and the moderate use of cooling aperients. This regimen was more strictly enjoined in the last months of pregnancy from a persuasion that an observance of it in the former months would avail little if neglected in the latter."

Lucas mentions a case of contracted pelvis where embryotomy had been performed in the two previous labours; under his treatment the next labour was remarkably less tedious and the child was delivered without difficulty. He gives other instances of the benefit of this treatment. This method of starving the mother to diminish the size of the child is usually attributed to Prochownick, who published a paper on the subject in 1901. It is interesting to find that it was first published by the Medical Society of London more than a century before. The method, of course, has its limitations and is very rarely employed at the present day; but I have recently seen a patient who was successfully delivered in America of a small child after adopting the treatment recommended by Lucas.

#### SYMPHYSEOTOMY AND PUBIOTOMY.

In the year 1772 Jean René Sigault published a paper, "An in partu contra naturam sectio symphysis ossium pubis sectione caesarea promptior et tutior?" Five years later, on October 1st, 1777, he first performed the operation on a patient named Souchot, delivering her of a living child, the mother recovering with the discomforts and inconveniences already mentioned. The Faculty of Medicine of Paris had a medal struck in Sigault's honour and in many directions there was great enthusiasm over the operation. But next year, in 1778, Piet reported that he had previously delivered the patient Souchot of a large child with prolapse of the cord without much difficulty, and thus took away a little of the credit of Sigault's achievement. Gradually the enthusiasm died down on the Continent and in England the operation was looked on with disfavour, mainly owing to the researches and writings of the Hunters and Denman. The first time this operation was performed in England was in 1782 by Welchman.<sup>1</sup> The child was dead and the mother succumbed.

It was only in Italy that the operation continued to be performed, though sporadically, till it was revived by Morisani in 1881 and by Pinard in 1900; the latter in 100 operations had a mortality of 12 per cent. for the mothers and 13 per cent. for the children. Since that date the division of the symphysis and its modification pubiotomy have been extensively practised on the Continent and to a less extent in this country, with a gradually diminishing rate of mortality. The reason why it has not been more in favour is that it inflicts considerable injuries on the mother and has a higher rate of mortality for the child than Caesarean section. It has the advantage that in a doubtful case it permits a trial of the effects of labour without increasing the risk of the operation and may be employed in a limited class of cases of slight pelvic contraction. In this country, however, the enthusiasm of some of its advocates appears to have evaporated. I have never performed the operation, and am of opinion that it is very rarely indicated if the cases of contracted pelvis are properly investigated during pregnancy. The disadvantages of symphyseotomy and pubiotomy have led to other operations for enlarging the pelvic cavity, such as excision of the pubic bones and of the sacral promontory; but these operations have not led to any practical results.

#### THE INDUCTION OF PREMATURE LABOUR.

Of this life-saving operation, purely English in origin, we have the first account in Denman's *Introduction to the Practice of Midwifery* (third edition, 1801, p. 394). It was given to Denman by Dr. C. Kelly, who informed him that

"about the year 1766 there was a consultation of the most eminent men in London at that time, to consider the moral rectitude of, and advantages which might be expected from the practice, which

met with their general approbation. The first case in which it was deemed necessary and proper fell under the care of Dr. Macaulay and it terminated successfully. The patient was the wife of a linen draper in the Strand. Dr. Kelly had himself performed the operation three times on the same woman and twice the children had been born living."

Denman defines the limitation of the operation in these words: "It is in those cases only in which there is a reduction of the pelvis to a certain degree and not beyond that degree that this operation ought to be proposed or can succeed." He mentions the case of a lady of title who had had four dead children at term. Labour was induced early in the eighth month of her pregnancy and the child was born alive and survived.

Denman induced premature labour by puncturing the membranes, and stated his opinion that the operation is perfectly safe to the person on whom it may be performed. Puncture of the membranes is still used by some obstetricians (for example, v. Herff) as a means of inducing labour; but the favourite method is the bougie method, first employed by Sir J. Simpson in 1854. It is usually described as Krause's method, whose publication, like Simpson's, is dated 1855.

The induction of premature labour has always remained an essentially British and mainly English operation. In France it was opposed by the great authorities Baudelocque and Capuron, and not till 1830 was it favoured by Stolz. In Paris it was first performed by P. Dubois in 1840, but was condemned on insufficient grounds by Pinard in 1900. In Germany Wiedmann wrote in its favour in 1779; his pupil, Wenzel was the first to perform it in 1804, and his paper with Froriep's commendation led to its adoption in Germany, where it is still practised, but is by no means a favourite operation. In Berlin it was first employed by v. Siebold in 1819. In the Scandinavian countries it was not performed till the year 1827. In America Whitridge Williams, of Johns Hopkins Hospital, Baltimore, states that he has never found it necessary to resort to the induction of premature labour in contracted pelvis. His erroneous reasoning in adopting this attitude has been pointed out by Dr. Herbert Williamson in an excellent article.<sup>2</sup> I will only add here that in his alternative treatment by Caesarean section Dr. Whitridge Williams finds it necessary to resort to the mutilation of the mother by hysterectomy with remarkable frequency.

From this brief historical review of the induction of premature labour it will be seen that the operation has met with little favour on the Continent of Europe and in America. If one inquires into the cause it is found in three factors—that the operation has been performed in unsuitable cases, at unsuitable times, and by unsuitable means.

The cases of contracted pelvis suitable for the induction of premature labour are those with a true conjugate diameter of not less than 3½ inches; the operation should not be undertaken before the thirty-fifth week from the last day of the last menstruation, and the bougie method of Simpson or rupture of the membranes is the best method for ordinary cases. Champetier de Ribes's bag may be required in special cases, though it has the great disadvantage (amongst others) that it displaces the presenting part. For a pelvis with a conjugate diameter less than 3½ inches in length Caesarean section is more suitable, though I have delivered by induction at the thirty-fifth week through a pelvis with a 3-inch conjugate a child who grew up to womanhood. The mother died some years later after an operation for cancer and the pelvis is exhibited to-night.

Carried out in the manner indicated induction of premature labour is an excellent operation, giving results to the child less favourable indeed than Caesarean section, but to the mother even better than those of natural labour at term. The operation has been repeated in one of my cases twelve times with the result of twelve living children. The larger the pelvis over the 3½-inch minimum the later the induction should be deferred, but for pelves with a 3½-inch true conjugate it is better generally to let the patient go to term unless the head is unusually large. It is important that the delivery of the premature child be left to the natural powers, forceps and version being particularly injurious to these infants.

Having had a large experience of this beneficial operation, having watched the upgrowing of some of these premature

the operation. As a result of this unfortunate experience Baudeloque was assailed with the most violent obloquy by Jean François Sacombe, an eloquent, witty, and scurrilous charlatan, who occupies such a remarkable position in the history of Caesarean section that a few particulars of his career may be worth mentioning.

#### J. P. Sacombe.

Sacombe was born about the year 1750 at Carcassonne. After studying obstetrics at Montpellier and in England under Osborn and W. Hunter he went to Paris to practise as an accoucheur. He gave out that he could deliver any patient with his hand alone, without the use of any instrument. He was especially bitter against those who performed Caesarean section, and from the year 1790 onwards he disseminated his views by lectures, pamphlets, and posters. In one of the pamphlets he pilloried Baudeloque as a "murderer," for which libel he was condemned to pay a fine of 3,000 francs. Unable to pay the fine, he fled from Paris, but returned under the altered name of Lacombe in 1813. Having lost his obstetric practice he gained a living by selling secret remedies. "Deserted by Lucina, he paid attention to Venus," wrote a work entitled *Venusalgia*, and died discredited and neglected in 1822.

In order to carry on his campaign against Caesarean section, Sacombe founded his "Ecole anti-Caesarienne" in 1798. Here lectures were given and an annual festival was held at which a silver medal was awarded to one of the pupils; on one side of the medal was the figure of Hercules slaying the hydra, with the inscription "No more Caesarean section"; on the other side a beehive and flying bees, and the inscription "Sacombe's anti-Caesarean School." The recipient of the medal had the privilege of embracing Madame Sacombe.

A statue of Bonaparte was set up in the school and Sacombe dedicated one of his works to him, and at one time praised the Consul for "muzzling the Caesarean tigers." In 1815, however, he was imprisoned for writing against the Emperor. Sacombe was a prolific writer, both in prose and verse. In his *Lucine Française* (1803) he gives an account of François Rousset, whose work on Caesarean section had been highly praised by Haller and Portal. Several faculties of medicine had disputed the glory of conferring a degree on Rousset, and Catherine de Médicis had appointed him her physician.

"However, I resolved," says Sacombe, "to overturn this colossal statue, to break it and to prove to my pupils that celebrity in medicine can only be desirable when based on talents and virtue. I will demonstrate that Rousset was neither a physician nor a surgeon, but a fanatic and ignorant criminal, and the vile instrument of depopulation of which the infamous Catherine de Médicis made use against the Protestants."

In his *Elémens de la science des accouchemens* (1802) he styles himself "Professeur de médecine et de chirurgie des accouchemens," yet he speaks contemptuously of accoucheurs as "hermaphrodites of the art" and "midwives in breeches." Of Clément, the first "accoucheur," he writes:

Clément dut au hazard sa vogue et son crédit  
Il enrichit moins l'art que l'art ne l'enrichit.  
Accoucheur des Laïs, en dépit de Lucine  
Clément fit fortune où maint amant se ruine.

Sacombe's *Elémens* contains a portrait of the author and a plate of the Ecole anti-Caesarienne, with a figure of the Caesarean hydra struck down "30 brumaire, an vii" (Fig. 2). Of this monster he writes:

"Born in the midst of the civil wars which desolated France towards the middle of the sixteenth century the Caesarean hydra, attracted by the odour of human blood, has raised again its hideous head amidst the scaffolds which crowned the soil of France at the end of the eighteenth century."

He ends his work:

"My task is complete; I have avenged Nature and consoled humanity in giving the death blow to the Caesarean hydra."

It was, however, not by the Ecole anti-Caesarienne nor its discredited founder that the performance of Caesarean section was rendered infrequent, but by the almost uniformly

fatal results of the operation at the end of the eighteenth century.

In 1866 Murphy found that of 56 operations in Great Britain 46 had terminated fatally (82 per cent.). Even as late as 1874 the maternal mortality was 54 per cent. in Europe and America.

#### Porro and Sänger.

In 1876 Porro (Fig. 3) introduced his method of amputating the uterus after the section. The effect of this, combined with Lister's antiseptic method, was to lower the death rate considerably, so that in Truzzi's great collection of all the "Porro" operations published up to 1901 the death rate was reduced to 24.8 per cent.

In 1882 Sänger introduced his method of suture, which still remains the favourite, and though various modifications have since been recommended, such as the incision into the lower segment and the subperitoneal and transperitoneal incisions, the Sänger conservative method with silk sutures carefully buried by a continuous peritoneal stitch has advantages over other methods in uninfected cases. The advantages of the Sänger incision and suture are (1) the rapid delivery of the child in an unanesthetized condition; (2) the operation can be repeated with safety; (3) adhesions and rupture are rare if the wound be properly sutured with silk.

#### Results of Modern Caesarean Section.

The results of the modern Caesarean section in non-infected cases are highly satisfactory. Thus Routh in 1910 found a maternal mortality of 2.9 per cent. in "clean" cases, of 10.8 per cent. in cases with ruptured membranes, and of 34.3 per cent. in cases where frequent examinations or attempts at delivery had been made. From those and from figures collected by Holland (who dealt with hospital cases only) it is seen that to obtain a low mortality rate it is necessary that the mothers should not be infected when operated on. In such cases the operation should be free from mortality, and in my personal practice has been so.

#### Abuse of Caesarean Section.

The safety of the operation in skilled hands has led to a great abuse of the operation by its performance in cases in which it is quite unnecessary and often quite unsuitable. I have known it proposed for a patient with a large pelvis solely because she was 38 years of age; she was easily delivered by Nature of a 9 lb. child. When we read of hospital staffs and even individuals performing a hundred Caesarean sections in a year, it is time to make a protest against unnecessary operative interference. The most marked instance of "meddlesome midwifery" is contained in a work by I. W. Potter entitled *The Place of Version in Obstetrics* (1922). This author delivered 1,130 women in the year ending August 31st, 1921; of these, 100 were delivered by Caesarean section and 938 were delivered by version. It is to be regretted that such a line of practice should be advocated, as it will inevitably be attended with disaster in the hands of less skilful imitators.

Francis Bacon commends as excellent for the advancement of learning the keeping of Registers of Doubts, with the caution that "when the doubts be thoroughly sifted and brought to resolution, they be from henceforth omitted, discarded, and not continued to cherish and encourage men in doubting."

In obstetrics there have been many doubts. But doubt that natural labour is in ordinary cases preferable to operative labour should have been discarded long ago.

In the *Boston Medical and Surgical Journal* of June 14th, 1923, there is a thoughtful and remarkable article on Caesarean section, in which the author says:

"In the minds of certain obstetricians or surgeons Caesarean section is the only method by which a self-respecting patient can be delivered and maintain her standing in the community."

He also states—

"that the mortality statistics of Massachusetts show that of the women dying during pregnancy and labour in a given year, approximately one-third die of complications which have been treated by Caesarean section."

Butter. Special attention should therefore be given to improving the general health, and especially the nervous health of beginners. If ocular balance was upset by glare, might it not be that the motor reflexes were embarrassed by strong cerebral impulses, and might the same not be true of intestinal or stomachic irritation? The speaker offered a distinct alteration in his oculomotor relations during a temporary attack of colic, and indeed the temporary spasm produced in children by worms might be classed in the same category. All this emphasized the importance of the general health. Another suggestion he offered was to supplement the tests in near vision already described by others on a scale more proportionate to the distances with which aviators had to do. Ought not, for example, version tests in distant vision to receive attention? Again, would it not be possible partially to reproduce the conditions required for landing, as, for example, to let a seated man descend rapidly with a rope, and let him pull a handle at the appropriate moment? He could be let down perpendicularly, or, better still, swingwise. It would not be so easy to make an appearance of the earth to rise up towards a stationary man, but perhaps even this might be achieved optically, as by the beam of a searchlight moving very quickly at right angles to itself.

Major CARTERS (Liverpool) had seen at Hampstead the result of Wing Commander Clements's training of cadets who had crashed and broken many machines, and was astounded at the results. Wing Commander Clements was not only an original worker who formed his own theories, but had the unique opportunity of putting his theories to actual test. However much his theories might be open to criticism, his results were facts and were beyond criticism. Major Carters hoped that Wing Commander Clements would remember that life is short, and would publish his methods and his results without long delay, as they would be of the greatest value to everybody interested in ophthalmology.

Major R. E. WRIGHT, I.M.S. (Madras), asked Commander Clements whether the methods utilized by ophthalmologists in investigating nystagmus produced by rotation were of value in connection with the examination of men in the air force. Such methods had been highly developed by ear specialists, and would appear to have a very direct bearing on experimental ophthalmology in the air force. With reference to the President's question as to glare and its effects in India, Major Wright knew nothing beyond what had already been published in works dealing with the subject. It was a very difficult thing indeed to put into concrete form the actual ophthalmological results of glare. Normal eyes in healthy individuals seemed to stand glare very well. There was undoubtedly such a thing as glare conjunctivitis, or suburn of the conjunctiva.

Mr. J. A. VALENTINE (Southsea) said that the amount of convergence necessary during a landing when the plane was some ten to twenty yards from the ground was less than a fraction of a degree; in a case of orthophoria with convergence insensibility there should be no difficulty in effecting this minute amount of accommodation necessary in approaching the ground. Was it credible that even a large amount of convergence insufficiency could make any difference whatever to an otherwise orthophoric aviator in effecting a landing?

The President congratulated the Section on the excellent discussion. Mr. Clements's work was an admirable example of how such research should be carried out. Whether one agreed with all his deductions or not was relatively immaterial, for a measure of criticism stimulated further research. His work also showed how any research revealed new problems which had to be investigated. He (the President) had had some experience of the visual problems which confronted all three services during the war. Investigations and experiments had to be carried out hurriedly and hastily, and during the stress of war, and practical results—often of doubtful validity—had to be obtained and acted upon.

These problems ought to be investigated during peace time, with the assistance of experts obtained if necessary outside the services. Funds had been made available for the air force, because the air force could not be efficiently maintained if such researches were neglected. Funds had also been found for industrial research, and allotted to the Industrial Fatigue Research Board. The problems which confronted the combatant services were of supreme importance, and he (the President) hoped that this discussion might stimulate the Government to provide the machinery and the means for solving them.

#### Openers' Replies.

Air Commodore D. MCXRO, in replying to the discussion, referred to the stimulating suggestions of Mr. Maddox, and said that whilst the services had contributed something to the discussion, speaking for himself, new aspects of eye problems had appeared to him since he came into the room, and he thought that the service members would take away a great deal to think about. Speaking for the air force, they were fortunate in that all these problems were submitted finally to the President of that Section himself, Sir John Parsons, who was a member of their Medical Advisory Board.

Wing Commander CLEMENTS, R.A.F.M.S., in reply said: The question of "master eye" was one having a great deal of bearing on a pilot's capacity to fly certain machines. It was usual to land looking out from the left side of the aeroplane. Further, some machines were notoriously "blind" right or left, and in the past enough attention had not been paid by designers as to whether a pilot's vision was restricted too much. With reference to "glare," Air Commodore Munro had said that the glare which affected landing ability was not acquired whilst in the air, but whilst on the ground prior to entering the aeroplane. Glare and the question of night-blindness might be taken together; all those suffering from glare, if not definitely night-blind, showed more or less signs of lengthened adaptation time to night conditions. Efficient convergence was considered important because it was thought that it was one of the essentials for appreciation of fine ocular muscle movements. It was his (the speaker's) fine ocular muscle movements. It was an automatic act, fusion was only attained by repeated trial and error in the stages of which had been lost to consciousness but not to subconsciousness, and that if anything affected the final adjustment it would show up as an error of judgement in consciousness, and would then cease to be automatic. With regard to the toxicity cases mentioned by Sir J. Parsons and Mr. Bishop Harman, he was certain that there was undoubted evidence of their occurrence, and he himself had quoted instances as a frequent cause of loss of consciousness. Regarding the value of rotation tests and nystagmus tests, laboratory sensations only gave information as to position in regard to the thing with which the person was in contact, but in an aeroplane during flight it was quite impossible for the labyrinth to give any information as to position in space. In response to the request for information about training methods, Wing Commander Clements gave the salient features in relation to the various types requiring treatment.

#### Resolution.

At the close of the discussion the following motion was put to the meeting by the President:

That this meeting of the Ophthalmological Section recommends that the Council of the British Medical Association press strongly upon the Government the need for research upon

is reason to believe that they are similar to those of the other afferent neurones except that their cell bodies may be smaller and their processes finely medullated.

The afferent neurone conducts nerve impulses into the central nervous system. Its axis cylinder, after reaching the brain or spinal cord, as a rule divides into ascending and descending branches, which in their turn give off other branches ending in synapses with the dendrites of other neurones. The path taken by the nerve impulse in the central nervous system is partly determined by the anatomical distribution of the axis cylinder carrying it, and partly by the character and resistance of the synapses it meets.

#### THE NERVE IMPULSE.

The nature of the nerve impulse is unknown. It is not an electrical current, but is immediately preceded by a temporary change in the electrical potential of that portion of the axis cylinder which is at the moment conducting the nerve impulse. Such change in the electrical potential is common to living tissues in a state of activity, and by suitable means can be demonstrated as a "current of action." The whole neurone does not go into activity simultaneously, but responds to a stimulus in a characteristic manner. The response takes the form of a nerve impulse which travels from the point of excitation at a definite rate of about 120 metres per second. The nerve impulses, though capable of following one another at a frequency of from 50 to 60 per second, cannot fuse because after the passage of each impulse the nerve fibre is for a minute fraction of a second in a refractory state, during which it is incapable of conduction.

The nerve fibre requires a supply of oxygen to enable it to maintain its power of conduction, but it shows no measurable sign of oxidation, no rise of temperature, and no fatigue, even after long-continued activity. Further, the individual nerve impulse, as shown by the work of Keith Lucas and Adrian, is practically invariable in strength. It obeys the law of "all or nothing." The weakest stimulus that is effective produces a maximal response in the neurone. In other words, there is no grading of the individual nerve impulse. The number of impulses carried in unit time may vary, but cannot exceed a maximum imposed upon the neurone by the length of the refractory period. The only exception to the constancy of strength of the nerve impulse lies in the fact that immediately after the refractory period there is a supernormal phase in the neurone during which the response is a little stronger. The nerve impulse is always of the same nature by whatever nerve it is carried. This principle is the basis of Müller's law of "specific energies" or "specific irritability." It means that the end-result of the stimulus of nerve is determined, not by the character of the nerve fibre, but by the nature of its ending.

If we assume that the neurone has no power of automaticity, and that it only conducts in a forward direction, we are driven to seek the origin of all nerve impulses in the receptors on the afferent side of the nervous system. Whether the first assumption is true or not for all parts of the nervous system, it is so as regards the production of normal sensation and of reflex action, and it provides a good working hypothesis for clinical purposes. The nature and site of the receptors become matters of special importance.

#### THE RECEPTORS.

The receptors are widely different in structure and possibly in the manner in which they convert the adequate stimulus into a nerve impulse. In some instances the receptor appears to be a part of the dendron of the first afferent neurone itself. In the olfactory mucous membrane the dendron of the olfactory cell forms a fine projection which is stimulated by chemical substances in solution on the surface of the olfactory membrane. In the retina the outer ends of the rods and cones, modified dendrons, are stimulated by light, and possibly the actual stimulus is again a chemical one, depending upon the decomposition by light of a photo-chemical substance in them or in their neighbourhood.

In other sense organs the receptors are not always a part of the neurone itself, but special organs with which the

neurone comes into close association. In the cochlea and vestibular apparatus the receptors are hair cells which are adapted to respond to a mechanical stimulus, and their response is converted into a nerve impulse in the neurone. Now nerve fibres are comparatively inexcitable whereas receptors respond to forms of energy which have no effect upon nerve, and which may be infinitesimally small in amount. The receptor is specially adapted to respond to some particular form of energy, and it acts as a transformer of this energy, and when necessary adds energy of its own in order to produce the excitation of the neurone. The most effective stimulus of nerve is an electrical one of a very definite character. The nature of the optimal stimulus of nerve—the "characteristic" as it was named by Waller—has been more exactly determined by Keith Lucas. It is not so much a matter of difference of electrical potential as of the rate at which the alteration in potential takes place. Changes in electrical potential of this nature occur in living structures when set into activity, and it is possible that this factor is made use of in the excitation of nerve by some receptors. The receptor is set into activity by an appropriate stimulus for which it is adapted by structure, the stimulus being of a physical or chemical nature, and the change of potential thereby induced in the receptor may be the actual cause of excitation of the adjacent nerve fibres.

The receptors of the body are divided into two main categories: the exteroceptors, which receive stimuli from sources of energy outside the body, such as light, sound, and pressure; and the interoceptors, which are affected by events taking place inside the body. The proprioceptors are an important variety of the latter, and are the receptors which are excited by the tension of muscle, ligaments, and tendons, and the action of gravity. The proprioceptors give origin to the reflexes concerned with the maintenance of muscle tone and the posture of the body.

Receptors are not provided for all forms of energy—for example, Roentgen rays and ultra-violet light—and unless appropriate receptors are present such forms of energy do not excite nerve impulses nor give rise to sensation or reflex action. They may exert an influence upon the tissues of the body, but not of a nature adequate to excite nerve impulses until damage to the tissues is actually done.

The same form of energy may excite different receptors, especially when it differs in degree. Heat affects the receptors in the skin, and gives rise to the sensation of heat. If the wave-lengths are appropriate they excite the receptors in the retina and the sensation of light results. The same stimulus may excite the production of more than one sensation. Heat applied to the skin may cause a sensation of heat and a sensation of pain; pressure the sensations of pressure and of pain. The two sensations may be ascribable to the action of the same stimulus upon different receptors, and the paths of the nerve impulses are then separate from their origin to their termination in the higher levels of the central nervous system. There are receptors which, when excited by an adequate stimulus, give rise to nerve impulses producing reflexes, but which are not normally associated with consciousness. Many of the interoceptors are of this nature, and initiate reflexes which are unaccompanied by sensation. On the other hand, the receptors which are concerned with the production of sensation may at the same time initiate reflexes. In the "conditioned" reflex the same receptor probably serves for both sensation and reflex. In some instances the same receptor gives rise to a nerve impulse which almost immediately spreads into two or more afferent channels and is carried to different parts of the brain. Light falling upon the retina excites its receptors, and the nerve impulses set up pass by different paths to produce the sensation of light and the reflex movements of the pupil. The retina is exceptional in that it contains several short neurones and intervening synapses, which allow an immediate spread of the nerve impulses, but an example of an immediate spread of the nerve impulse is also found in the "axon" reflex. Certain receptors in the skin give origin to nerve impulses which pass to the central nervous system and at the same time spread along branches of the axis cylinder.

Memoranda : MEDICAL, SURGICAL, OBSTETRICAL.

AN UNUSUAL CASE OF PNEUMOTHORAX.

The following notes of an uncommon condition seen to be worthy of publication. The patient was a schoolboy aged 18 years, who received an injury to the chest while playing Rugby football.

The family history is as follows: Maternal grandfather lived to over 60 years and paternal grandfather died aged 66. Father alive and well aged 55 years, mother 55 years and healthy. Two brothers alive—one aged 20 years healthy, the other aged 12 years described as delicate. One sister died at 2 years—cause unknown. There is no known history of pulmonary tuberculosis.

The patient had pneumonia in 1914, followed by whooping-cough, otherwise he has rarely been ill.

He was playing football on November 17th, 1922, and was in the act of scoring a try when an opponent knelt heavily on the back of his chest. He felt a very slight pain but no dyspnoea. The next morning he complained of slight pain in the left side of the chest over the precordium. There was no evidence of fractured rib. In two days he felt perfectly well. He played football again on November 24th and, after the game, complained of slight shortness of breath.

I found the following physical signs in the chest: There was alteration in the percussion note over either lung, nor any change in vocal fremitus or resonance. Over the right lower lobe posteriorly there was an area of high-pitched distant bronchial breathing. I sent him to Dr. A. J. Cleveland of Norwich for an opinion, especially having in view the x-ray findings. The following are his notes of the case:

"I saw this patient on November 28th, 1922. I found that both lungs were resonant all over. The heart apex was just outside the nipple line. Over the right lower lobe there was a fair-sized patch of bronchial breathing. I got a modified 'bell sound' but no metallic tinkling. With x rays it was obvious that there was a moderate-sized pneumothorax at the outer and lower side of the right pleural cavity. I could find nothing to suggest a fractured rib. In 1914 he had a bad attack of right lobar pneumonia and whooping-cough, and I conclude this must have left some weakness of the alveolar walls, which gave way under the strain caused by a heavy man falling on his chest. I saw him again a fortnight later and the physical signs were much less definite and, after another fortnight, I could not detect any evidence of pneumothorax either with x rays or the stethoscope. At no time could I find any evidence of pulmonary tuberculosis. When I last saw him he appeared to be in excellent health."

He returned to school on January 20th, 1923 (he had been resting quietly at home till then). He began to play hockey about a fortnight later and played regularly until the end of March. I examined his chest several times and could not detect the slightest abnormality.

L. S. HENRY, M.B., Ch.B., Edin., Medical Officer, Greenham's School.

TWO CASES OF LIGHTNING STROKE.

These two cases are considered worthy of record as I have not seen a similar train of symptoms recorded elsewhere.

Both men were standing in the door of a cowshed while a violent thunderstorm was in progress. A flash of lightning struck them, throwing both to the ground, one on top of the other. They were seen about half an hour later. Both had aporosect markings on the left side of the face and neck of an erythematous nature. The marks lasted for about twenty-four hours.

One was rendered unconscious by striking his head on the brick floor. As a result of the fall the injury he complained of blindness in the affected eye and there was considerable conjunctival suffusion. Opacity of the lens was not obvious until about the tenth day; it then gradually increased, and the eye has been operated on.

Both men complained of pain in the supraciliary region radiating down the arm. Weakness of the affected limb and sensations of pins and needles were present for two or three weeks, but this condition cleared up, leaving no disability.

I. H. LLOYD-Williams, M.B., B.S., Burgess Hill, Sussex.

spouse rubber buffer to support the forehead and shield the eyes from extraneous stimuli. For gun-sighting telescopes the experimental firing with this device took place at sea in H.M.S. *Canterbury*, off Portsmouth, and I watched the successful issue of the trials with great interest.

NAVY CODE OF LIGHTING.

Service Light.

1. In order to see well, several factors are concerned—fair health, good eyesight, normal retinal adaptation, sufficient light flux, adequate distribution and direction of light, and quiet contrasts.

The eye.—Vision is a complex affair, the eye being highly trained and delicately sensitive in retina and iris to the balanced reversible electro (chemical) reactions resulting from impact of light energy around the sensitive retinal terminals of the optic nerve. The eye is a trigger, as it were, that starts into action nervous impulses which arrive at the cortex of the brain where perception results, and whence highly complex co-ordinated actions originate. It is not the eyes only, but the whole mechanism of vision that is liable to fatigue under conditions of faulty illumination and mal-hygiene generally.

2. In any system of lighting, light will be reflected from surrounding objects, desk bulknheads, sides and impedimenta. Light so reflected will vary in quality and amount and such variation is important and is calculable in any system under the term "coefficient of utilization," usually 0.2 to 0.6 according to size, shape and tinting of enclosing surfaces.

3. The intensity of light, measured in lumens (1 lumen = 0.929 c.p. per square foot), to be maintained, should not vary appreciably from the following—with 52 per cent. margin for deterioration on instantment. [The table is omitted.]

4. Glare, glitter, and, on the other hand, gloom, are to be avoided. Source of light should be shaded, so that naked direct light subtends, at the eye, an angle of 75 degrees or thereabouts (broad angle) with the visual horizon, when the eyes are directed straight forward.

5. Lamps should be mounted overhead in closer range (1 to 1) than working plane to distance apart of the lamp as 1 is to 1.5.

6. *Done Lighting*.—The principle of naval lighting is thus direct (ensuring economy) with total absence of dazzle (minimizing eye fatigue) and amounts in effect to a lowering of the "light ceiling"—the light issuing from a number of unobtrusive domes.

7. On the area of the working plane light should fall uniformly, and not vary over that area more than 4 to 1. Brightness contrast should not exceed the ratio of 20 to 1. For example, on a billiard cloth, beneath a shaded light source, the red and white balls receive the same uniform flux of light, but the whites reflect so much more light than the red ball, that annoyance is caused if total flux be excessive.

8. *Police Lighting*.—[Details omitted.]

9. *Chart-room illumination* presents a threefold problem: (a) day lighting; (b) partial day and artificial lighting; (c) artificial lighting. In (a) a curtain or blind or green frosted glass houseable shutter to be provided for sun glare. In (b) dome-shaded direct light from the upper left and rearward side of the navigator. This should be on a dimming resistance so that light flux may be reinforced when, in (a), flux of daylight is insufficient. In (c) as in (b) with added attention in providing an adequate coefficient of utilization.

10. *Submarine*.—to be illuminated internally as in 1918 recommendations—care being taken that light flux be sufficient in amount and controlled by accessible switch, on rheostat. For use in harbour dome-shaded (75 degrees broad angle) lamps may be added. *Emergency lighting* by self-luminous radium bromide (foresal) spot lighting in vermilion-tinted fluting on levers, dial pointers, level surround and salient lines of control room (experimental research advised).

11. *Refecting* surfaces should be free from glitter, of matte surface and clamping bare. Reflecting factor should be low from surfaces below and 30 degrees above the horizontal eye level—and high from surfaces above that angle.

12. Controlling levers and switches should be easily visible and naturally accessible.

13. In a bright light the eye is adapted or tuned to a high level of brightness and visualization remains good if variation in brightness be neither great nor rapid. Figures given in this code relating to artificial lighting must be X 2 for day-lighting at least, and partial day-lighting necessitates reinforcement by artificial.

14. A properly trained staff should be held responsible by the captain for cleanliness and condition of lamps, shades and reflectors.

We regard pain as a sensation which under certain conditions is superadded to the reflex, and the nerve impulses giving rise to pain we regard as excited by the same receptors and carried into the central nervous system by the same afferent neurones as those which bring about the reflex. Pain may be readily added to the reflex, as in the case of the afferent neurones from the cornea, or more rarely added, as in those from the heart muscle. The harmful stimulus, as has been shown by Sherrington, takes precedence of all others in bringing about its distinctive reflex, even in the spinal animal in which there can be no perception of pain. These observations appear to us to point to the reflex as the more important end-result of the harmful stimulus. In certain cases of injury to the spinal cord where areas of hyperalgesia are found in the skin the slightest stimulation of the latter results in pain. We cannot but conclude that here we are dealing with a central change, and that the nerve impulses excited at the periphery, which in the normal individual would cause no pain, now do so because of their more ready access to the pain tracts in the spinal cord. The actual cause of this increased passage of nerve impulses into the pain tracts appears to us to be explainable by a decreased resistance in the synapses between the endings of the afferent neurones and the dendrons of the neurones which constitute the pain fibres of the spinal cord. We know that the nerve impulses giving rise to pain are carried by fibres which decussate to the opposite side of the spinal cord soon after the impulses have reached the cord, and that this decussation is not made by the incoming afferent neurones. Consequently there must be a synapse intervening between the incoming afferent neurone and the neurone which carries the impulses upwards on the opposite side of the spinal cord. This synapse, guarding as it were the entrance to the pain paths, is of great significance, for it interposes a resistance which is probably very varied for different afferent neurones, and is in each case susceptible to those changes which are characteristic of the synapses in general. So far as we know the afferent fibre on arrival in the lower level of the central nervous system gives off a number of branches and makes connexions with other neurones. Pathways are thus provided for a great many reactions.

It seems to us that neither pain from tissues endowed with common sensibility, nor from the viscera, requires special nerve fibres from the periphery, and that the analysis of the afferent nerve impulses takes place in the lower level of the central nervous system. Pain from tissues endowed with common sensibility becomes educated, capable of localization, and modified by other sensations. Pain from the viscera is comparatively rare, uneducated, unmodified by other sensations, and the nerve impulses which cause it, on coming into the lower level of the central nervous system, excite the same neurones in the pain paths and give rise to pain which is referred to those areas of higher sensibility with which it has by education been associated.

There is, therefore, no necessity to postulate the separate existence of special receptors and special nerve fibres for the sense of pain. It is not indeed reasonable to assume that structures like the ureter and other viscera are provided with special receptors and special nerve fibres to meet a pathological event which may not occur for generations. The stimulus which is adequate to excite pain in the viscera or elsewhere may do far more than this. It sets up nerve impulses which spread widely in the lower level of the central nervous system, and may give rise to nausea, vomiting, sweating, vasomotor, cardiac, respiratory, and other reflexes, or even shock. Pain may or may not occur in association with any or all of these symptoms. Pain is a concomitant very often, but is not the cause.

Pain is one of the most important manifestations of ill health, and when it occurs is of special diagnostic value because the site of its excitation can be more or less definitely located. In this way a clue is given to the site and cause of the disturbance which is not to be obtained from the other symptoms occasioned by the spreading of the nerve impulses in the central nervous system.

## PELLAGRA IN CHILDREN IN ENGLAND. (With Special Plate.)

BY  
ROBERT HUTCHISON, AND DONALD PATERSON,  
M.D., F.R.C.P., M.B., M.R.C.P.,  
PHYSICIAN, PHYSICIAN TO OUT-PATIENTS,  
HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET.

Our object in reporting two cases of pellagra in children is to draw the attention of clinicians in this country to the fact that pellagra is endemic in England.

The diagnosis, except in typical cases seen during the spring and summer months, when the rash is well marked, is not easy, and a considerable number of cases probably remain undiagnosed on this account. In 1913 and 1914 Dr. C. R. Box described three cases of pellagra in children, two of them fatal. In one of these cases the pathology was described in detail by Sir Frederick Mott. All of these children had lived throughout life in England.

### CASE I.

Edna S., aged 6 years and 10 months, admitted to Great Ormond Street Hospital, April, 1923. The complaint was loss of walking power and shaking of the limbs. This had been noticed for six months. The family history appeared quite normal, no other person being affected. She was breast-fed for six weeks, then put on Nestlé's milk up to 11 months, since when she has had the same food as her parents. She had meat first at 3 years. She had always had plenty of milk, eggs, vegetables, and fruit. She was always fond of "cornflour" and would take nearly half a pint daily. She seemed a healthy child up to the age of 3½ years. She had lived at Little Blackenham—five miles beyond Ipswich—all her life except between the ages of 4 and 5½ years, when she had lived at Walthamstow. She had had "eczema" every year, starting in the spring. It was first noticed to occur after an illness, said to be "meningitis," at 3½ years of age. This illness lasted three months and was accompanied by fever and drowsiness; recovery was gradual. The rash appeared as the child got better. It appeared on the hands, feet, neck, and face. It appeared on the knees last year for the first time. It usually lasted four to five months, appearing first in March. In July, 1922, the child complained of "giddiness" and began to fall about. This came on suddenly, the child falling down when out walking. She did not lose consciousness and the attack lasted one and a half hours. A month later she had two similar attacks.

*Present illness.*—The patient was comparatively well until six months ago, when she gradually ceased to walk more than a few steps, and tremor of her hands and arms developed. She walked with the aid of the furniture. She complains of pains in her head which seemed to start at the back of her neck and shoot over her head. Her eyesight failed and she could not recognize objects across the street. She had some frequency of micturition by day and night.

On admission, the child was miserable but well nourished. There were patches of dermatitis on the face, neck, hands and inner surfaces of the arms, knees, and backs of the thighs. The tonsils were large and injected. There was incontinence of faeces. The child had a tremor of her arms and hands. The pupils were equal and reacted to light. No cranial nerve palsy was noted. All her deep reflexes were increased. The plantar reflexes gave a clonus response, and the abdominal reflexes were not obtained. No ankle-clonus was elicited. There appeared to be a certain amount of anaesthesia to pin-pricks over the legs and abdomen, but there was no definite distribution and it was difficult to be sure. Her Wassermann reaction was negative. The cerebro-spinal fluid was normal. Her mental condition was very backward and she seemed to have the feeling that she was continually falling. Nothing definitely pathological was made out from an examination of the fundi. The urine contained a few cells and a trace of albumin. The urea concentration test showed a normal output of urea by the kidneys. The blood urea was normal: 37 mg. per 100 c.cm. The rash which was present had the appearance of a dermatitis produced by exposure to the sun. A test meal showed a well marked reduction of the total acidity of the gastric juice. No free hydrochloric acid was present.

The patient was seen by Dr. L. W. Sambon, who stated that the distribution and character of the rash and nervous symptoms were typically those of pellagra. The child became much worse during the first week in May, 1923, and passed into a state of coma and died. Unfortunately no necropsy could be obtained.

### CASE II.

Helen S., aged 10 years and 9 months. Admitted to Great Ormond Street Hospital, July, 1922. The complaint was progressive mental deterioration and inability to walk, and in addition a rash on the hands, feet, face, and neck which came in the spring and summer and disappeared in the winter. She has lived all her life at Acton, a suburb of London, without leaving the district. The mother and father are both alive and well. The patient is

KLATZSCH'S THEORIES OF EVOLUTION.

similarity which exists between all the races of mankind and the structural differences which separate man and anthropoid, to say nothing of the structural agreement which links anthropoid to anthropoid, will at once realize the almost childish impossibility of Klatzsch's theory of a separate phylum for the orang and Mongol on the one hand, and another for the gorilla and negro on the other. Time after time his guesses have been riddled by fact- and argument.

But fact and argument fell from Klatzsch as water from a duck's back. In this volume all the old unsupported statements are reproduced as if they were undeniable gospel. He again reiterates the belief that man has retained, in the form of his teeth and shape of his palate, a primitive heritage, borrowed from the lower of primates, whereas the evidence of embryology and of fossil man leaves no doubt that the human teeth and palate are reductions from a true anthropoid form. We the characters shown by a human foetus are ancestral and primitive, the truth being that in the majority of instances such characters are recent and new. He even cites the long period during which the human child is dependent on the mother as embryonic and ancestral at bottom. Klatzsch's theory is a relapse to the wild doctrine of Lord Monboddo, who regarded apes as degenerate kinds of humanity. In spite of the many false doctrines promulgated in this book there is much also to be praised. Klatzsch may have been eccentric in his support of evolution, but he was never half-hearted. He had the most unshakable belief in Darwin, in Huxley, and in the Australian aborigine as well as in himself. He had no fear of any problem; he broached the origin of man, his religion, his clothes, his home, his marriage, his morals—all that is man and of man. He may raise in his expert reader a powerful sense of opposition but he never permits him to go to sleep.

The translation reads easily, but there are certain points in which an expert anatomist could have given the translator some help. The femur of the poor man of Java should not have been printed upside down: the turbinate processes of the nose should not have been called "muscles," nor is it right to speak of the external ear as a "muscular shell"; nor should the cortex of the brain have been labelled as motor, sensitive, and sensory; nor the anterior belly of the digastric muscle described as a "double-bellied chin"; nor the ventricular pouches described as coming "in" under the vocal cords; nor the upper end of the pre-central convolution be described as "lying nearest to the skull"; nor the skull of the Combe Capelle man as being 200 cm. long—that is, ten times too much.

The type is large and clear, the illustrations well printed, but the book, if light to read, is terribly heavy to hold in one's hands.

DISEASES OF THE NERVOUS SYSTEM.

To produce in one volume a complete textbook of neurology and psychiatry and to keep it up to date is an ambitious task. Drs. JELLINEK and WITTE may fairly be congratulated on the result of their labours, which appear as a handsome volume replete with figures and diagrams. Their confessed aim has been to treat the nervous system and its diseases as a whole and thereby to bridge the gulf between nervous and mental diseases, which exists in many textbooks. In this book may be found a wealth of information fully illustrated by photographs and diagrams and admirably supplemented by reference to the literature incorporated in footnotes.

The general arrangement of the work and the classification of the material is good, though on a closer examination certain disadvantages appear. Thus the chapters on methods of examination are perhaps unnecessarily long and contain matter which would be more appropriately placed under the diseases of different parts of the nervous system. In some respects there has been an unequal treatment of material. Thus, for example, while eighteen pages

the end of last century, when Professor Gustav Straßburg was demonstrating that *Xenodermus* represented a distinct species of humanity, he in his investigations by a young anatomist from the forced himself on the attention of the world by the dogmatic, almost overbearing, way he expressed his opinions. His name was Gegenbaur. He was born in 1865, and had been modelled himself on Waldeyer. Like was capable of doing good work and also of evil of finality to the most rash kind of support. Like Haeckel, Klatzsch made the problems re-case with his prototype, was careless whether cases' origin the chief interest of his life, and, took his colleagues with him so long as he could ear of the public. Klatzsch, indeed, carried professional work the bearing and methods of a this, and the frontispiece of this posthumous work, *The Evolution and Progress of Man*, his physique was in keeping with his professional

best German professor had an immense work. Having made his preliminary comparison remains of the Neanderthal and modern types which he published voluminous reports—we find in England and studying the kinds of stone which ancient men of those countries made. Then he hurried off to Australia and neighbourhood study living men of the most primitive existing a rightly perceived that in no other way could a picture be formed of man's life in Europe during his time. Then in 1866 he was back again in Europe to of anatomy in Breslau, and in time to see the Haeckel's mandible unearthed and to help his in France.

Thus we see that Klatzsch was eminently qualified as actual experience is concerned, to write the evolution of man. His death in 1916, at his treatise on man's evolution—written purely and audience—had to be completed by his friend, Heilborn. It is this treatise which has been by Mr. Joseph McCabe and now published in the doctrines which are here preached with such assurance rest on a most slender basis of fact who know to undertake the thankless task of Neanderthal man Klatzsch was impressed, raising them to be erroneous. When examining so, by the number of points in which they the corresponding bones of the gorilla. He be-ould recognize a similar combination of characters skeletons of robust kinds of West African to account for these common characters he supposed a single ancestral phylum. Without branches of the gorilla, *Xenodermus* man, and the African geological support be supposed that this ancestral is represented—not by an anthropoid stock—but aape kind of being and that the gorilla was a representative of this humanoid ancestral stock. represented a resemblance—a very superficial one—of orang and the Mongolian races of Asia. To this resemblance he supposed that the orang, the Australian aborigine—whom he almost well as the European, represented an anthropoid stock from his purely hypothetical ancestral stock. Anyone familiar with the intimate structural

tion and progress of mankind. By Professor Hermann J. Joseph McCabe. London: I. Fisher Unwin, Ltd. 1923. 319, 311 figures, 28s. net.)

and onset of symptoms; the nature of the injury itself and the manner of its infliction.

First, as to the causation of the original injury, the appearance of the bones at once shows that a blow from a stick was not the causal factor. The acute, sharp-edged depression of the posterior and lower margin of the main area, the shelving of the floor, and the characters of the floor indicate that a blunt rounded instrument of heavy nature and small striking surface was used. Such weapon was in all probability a hammer or the blunt end of a fass (a kind of grabber used by the fellaheen in their work and a common instrument of offence). The blow was struck from the front by a right-handed man, the weapon being swung laterally. One blow only was struck, the forward drive of the weapon causing bending and compression of the skull, and bursting of the fronto-parietal suture was the natural consequence. The anterior and posterior fissures were caused simultaneously, the first by the bending at the site of impact, the second arising when the opening suture reached a point in the bone where it became thin enough to offer less resistance than the suture. This is a common feature of skull fractures.

Secondly, the rapid recovery after injury with definite pressure on the cerebral cortex is relatively common in this

country, and we regularly see cases of fracture of the skull, which in Europe would appear hopeless, in which recovery takes place without sequelae and without medical attention.

Thirdly, the sudden onset on May 25th of aphasia of the right limbs, followed by paralysis of the right side, indicates either rapid damage to both the motor area and Broca's speech centre or to the fibres passing from such areas, and as the softening was most marked about the optic thalamus and caudate nucleus we may assume that the motor and sensory tracts in the internal capsule were affected.

Such a condition would naturally lead to the diagnosis of thrombosis of the middle cerebral artery with consequent softening of the parts supplied. There was, however, nothing to indicate that there was any disease of the vessels whatever, and no reason for either thrombosis or embolism, the slight amount of thickening in the small arterial vessels being quite insufficient to account for thrombosis. The presence of septic foci in the softened area, the localization of this area under the old fracture, the absence of other disease, injury, or other cause, raises the assumption that the old injury to the skull and brain was the cause of cerebral necrosis and death after a period of quiescence of eleven years.

### PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, 1923.

#### SECTION OF RADIOLOGY AND ELECTROLOGY.

S. GILBERT SCOTT, M.R.C.S., L.R.C.P., President.

#### DISCUSSION ON THE X-RAY EXAMINATION OF THE URINARY TRACT.

##### OPENING PAPER

BY

ROBERT W. A. SALMOND, O.B.E., M.D., Ch.M.,  
D.P.H., D.M.R.E.,

Honorary Radiologist, University College Hospital, and Institute of Anatomy, University College.

(With Special Plate.)

SINCE the advent of x rays urology has undergone an enormous advance in more accurate diagnosis. This advance has only been obtained by the co-operation between urologists and radiologists. In the earliest years of radiology it was thought almost sufficient if a shadow of a stone could be demonstrated; but as years have passed, experience accumulated, and technique made more perfect, very much more is expected of the radiologist, and, in the more obscure cases, the technique has to be much elaborated. For some years only a positive result was of value, but now a negative one is, or should be, of almost equal value. The success of x-ray examination of the urinary tract may be said to depend on two main factors: (1) proper technique, and (2) accurate interpretation; the latter can only be got by combining the experience of the radiologist with that of the urologist.

As the technique is so important it will not be unprofitable to deal with it in full. As regards the x-ray apparatus, this should be capable of making the correct exposure in a fraction of a second, or at most in two or three seconds. The more rapid the exposure the less time the patient has to bear the compression and the easier it is to ensure immobility of the kidneys with resulting sharpness of outline. If the outfit is not so powerful it is still possible to do good kidney work with longer exposures, provided the kidneys are kept at rest by proper compression. Even with rapid exposures it is better to apply some form of compression for the purpose of displacing the coils of intestine to one side or the other, and so giving

a less thickness of solid parts to be traversed. A pneumatic bag which can be blown up to various degrees of distension is very satisfactory for this purpose.

If the examination is to be of any value it is necessary that the patient be prepared beforehand. For this two days should be allowed, during which he keeps on light diet and takes an aperient on each of the two evenings preceding the examination, so that the bowels are well cleared out. Early on the morning of the examination an enema should be given and as light a breakfast as possible taken. For the patient's comfort it is therefore better to make the examination early in the day rather than late. As regards the aperient, it does not matter much what is used, although some avoid castor oil as causing too much distension of the bowel with gas. Preparation of the patient, however, should not be overdone, as it is believed that if the intestines are empty and quite collapsed it is more difficult to show the outline of the kidney than if a certain amount of gas is present.

The patient having been properly prepared, one is ready to make the exposure. The tube should be soft rather than hard, with just sufficient penetration to get through the parts. The patient may be lying on his back or on his face according to the radiologist's method of technique. If the patient is supine the film is placed under his back in such a position that the last two ribs and the top of the iliac crest will be included. It is important to observe whether the skin of the back is free from papillomata or scars, and that it is in close apposition to the film. This can generally be managed when the compression is applied, or by some little manipulation, such as raising the knees or shoulders or both.

The tube should be tilted so that its extension tube points under the costal cartilages and thus avoids any calcification which may be present. As the centre of the kidney is normally at the level of the second lumbar vertebra the central ray should pass through this level, so that the kidney outline will show the least amount of distortion. It is immaterial whether both kidneys are done simultaneously on a larger film or whether each one is done separately, but it is most essential that the entire urinary tract of both sides should be done in all cases. Cases turn up every now and then in which the pain from a stone is referred from one side to another, and if both sides are not examined the examination would be more misleading than if it had not been done.

The films of the kidney region should show clearly the whole of the kidney outline, the last two ribs, the transverse processes of the lumbar vertebrae, outer margin of psoas muscle, and part of the crest of the ilium. The writer prefers to use unscreened films, but there is no objection to screens of the first quality such as Patterson's.

second lumbar vertebra with the calyces projecting above and below like horns.

Pneumo-pyelography is a similar method to the preceding except that oxygen is used instead of the opaque solution. The advantage claimed is that it does not obscure the shadow of a stone in the kidney pelvis as an opaque solution does. It is also said that the oxygen is more permeable than the solutions, and so will pass a constriction or obstruction more readily. The disadvantage is that any gas in the intestine overlying the kidney may be confused with the oxygen in the pelvis and calyces.

Ureterography is the outlining of the ureter by an opaque solution. It is of value in showing dilatation of the lumen and also kinks. For the demonstration of kinks it is better to withdraw the catheter well down into the bony pelvis and then inject the ureter. If the catheter be left in the ureter it acts as a splint and may obliterate any kink. Some kinks can only be made visible with the patient in the upright position.

In regard to cystography, while occasionally a bladder full of normal urine will show distinctly on the film, one cannot depend on this to show its outline. To demonstrate this it is usual to fill it with some opaque solution, such as 10 per cent. sodium iodide or an emulsion of barium and oil, or even air, although the last is not without its dangers. In this way any filling defect due to a growth inside the bladder will cause an irregular outline. It should be remembered that blood clot may sometimes cause a filling defect. A diverticulum, if it projects above the upper outline of the bladder, will be seen, but films taken at different angles may be necessary. Cystography is of special value in determining the shape and position of the bladder, the presence of diverticula, and the diagnosis of hydro-ureter, with incompetence of the uretero-vesical valve. It is also helpful in the diagnosis of calculi in the prostatic or prostatic urethra. The urethra does not lend itself well to the injection of opaque solutions, as it is difficult to maintain any pressure of the fluid.

Before passing to the important question of interpretation and differential diagnosis I would like to state briefly but emphatically that the photographic technique in urinary work probably requires more care and skill than in the examination of other parts.

One has next to deal with the interpretation of the various shadows found in the region of the urinary tract and their differential diagnosis, and also to consider the abnormal shadows of the outline of the kidney or bladder. It will perhaps be best if they are discussed under the headings of kidney, ureter, bladder, and urethral regions.

### I. Renal Area.

The normal position and size of the kidney should be clearly visualized in one's mind. Its size will, of course, vary with the size of the subject, and it is at present a matter of personal experience as to whether a kidney is thought to be larger than normal. Marked variation in size is found in various individuals, but there is usually very little difference in the size of the two kidneys in the same individual. This is of great help in the diagnosis of enlargement, for any appreciable variation in the size of the two kidneys should be regarded as distinctly pathological. The movement of the kidney in full inspiration and expiration varies from one to two inches in ordinary individuals. It is essential that the outline of the kidneys is shown on the film, for if an abnormal shadow is seen in either loin but clear of the kidney outline, then obviously it cannot be a renal calculus.

Kidney stones are characterized by being seen superimposed on the shadow of the kidney; they move with the kidney on respiration—in other words, they maintain a constant relation to some part of the kidney on expiration and inspirations; they are usually of homogeneous density, and have sharply cut outlines. The horn-shaped stone filling the renal pelvis and the branching stone filling the pelvis and calyces are quite characteristic. If seen on the screen their direction of movement with respiration is downwards and outwards. In the lateral view they are seen superimposed over the bodies of the first to the third lumbar vertebrae, although occasionally a stone may lie

behind or just in front of the vertebrae if the kidney is enlarged.

There are other conditions which cause definite shadows in the renal areas and which must be differentiated. The following are the most important:

- (a) Intestinal contents, including shot from game.
- (b) Calcified abdominal glands.
- (c) Gall stones.
- (d) Calcification in a tuberculous kidney.
- (e) Calcification in a malignant kidney.
- (f) Papilloma on skin of the back.
- (g) Foreign bodies.

Intestinal contents are due to inefficient preparation of the patient, and, unless the patient has been taking bismuth, are usually not so dense or so definite as a stone. The easiest way to clear up the question is to repeat the examination after further purgation. Shot eaten in game have been mistaken for stone.

Calcified abdominal glands may be very confusing, and may be found over any part of the urinary tract. The gland itself is rarely of any size, but when a group is clustered together the shadow may appear like that of one large gland. The density of a calcified gland is not homogeneous but irregular, due to the deposition of the lime salts in the areas of necrosis of the gland. For this reason they usually present a somewhat mottled appearance. They may be nearly as dense as a kidney stone, and are usually denser than a gall stone. The chief characteristic of a calcified abdominal gland is its great mobility. If two separate plates are taken with compression the position of the shadow will almost always be seen to show a great variation; in fact, it may be quite outside the field of one of the two plates. In a lateral view the shadow of these glands is nearly always in front of the vertebrae, but Thurstan Holland has recorded a case where a calcified gland lay against the front of the kidney and moved with it. In such a case it would be exceedingly difficult to differentiate it from a renal stone.

Gall stones are, of course, found on the right side. Their characteristics are a clearer central nucleus with a denser peripheral area; occasionally they are dense all through. The picture of multiple small faceted stones in a distended gall bladder is quite characteristic. Their density is rarely as much as either a renal stone or calcified gland. Under fluoroscopy their movement with respiration is more vertical than kidney stone. It is of immense value to get a film showing the outlines of both the kidney and the gall bladder. In this way alone it is quite possible to exclude renal stone. If the shadow is superimposed on that of the kidney, then a lateral view is of the greatest value in differentiating. A gall-stone shadow is well in front of the vertebral bodies, whereas a renal stone is usually level with the bodies or behind them. A lateral view in conjunction with an antero-posterior view is of more value than stereoscopic in the diagnosis between gall and kidney stones.

Calcification in a tuberculous kidney shows as an irregular calcification in its substance. It is rarely so dense or so well defined as stone, and usually the kidney outline will be seen to be enlarged.

Calcification in a malignant kidney is more rare, and presents much the same appearance as the last mentioned. The outline of the kidney will almost certainly be enlarged and its regular bean shape altered by the growth.

A small papilloma or wart on the back may cause a shadow exactly similar to that of a stone. Previous inspection should prevent any error.

With regard to foreign bodies, I have seen more than one case of a piece of shrapnel which had been thought to be a stone in the kidney. We had a case at hospital two years ago which was diagnosed by x rays as a stone in the kidney, and on operation was found to be a piece of shrapnel partly embedded in the kidney tissue and partly free in the renal pelvis, the latter portion having become encrusted with phosphatic deposits.

### II. Ureteric Region.

The normal position of the ureter is along or just internal to the tips of the transverse processes of the lumbar vertebrae, from the second down to the sacral

# MOTOR NOTES FOR MEDICAL MEN.

BY H. MASSAC BUIST.

## FEATURES OF THE FRENCH MOTOR SHOW.

The eighteenth international automobile salon in the Grand Palais will close to-morrow (Sunday, October 14th) and the seventeenth international passenger car show promoted by the Society of Motor Manufacturers and Traders, under the patronage of the King, will be opened to the public at Olympia, Kensington, on Friday, November 1st. But it will be preceded, on Monday next (October 15th), by the yearly international motor cycle show, which will, therefore, be the first of the motor exhibitions to be held in the enlarged building. The Paris Motor Car Show is purely French as regards 85 per cent. of the exhibitors. The British industry is represented by two makes of cars only, the Austin and the Rolls-Royce, the 7-h.p. chassis of the former make being the only example made in this country with a 4-cylinder engine of 1 litre capacity only, whereas French builders make several machines in this category. Owing to the state of the exchanges and to the 45 per cent. import duty, the British exhibitors in Paris are in much the same case as the American—they can be there for the sake of show, scarcely for business. General Motors, the great corporation that produces Chevrolet, Buick, Oakland, and Cadillac vehicles, is represented by a fine exhibit, especially of Buick and Cadillac machines, the three larger makes having brakes to all four wheels; this is a new feature of many American-made cars, as will be seen at Olympia, but a familiar thing in many of the cars of the leading French makers. No British exhibitor shows any chassis with four wheel brakes in Paris, though many will be standardizing them or offering them as an option at Olympia, including Armstrong-Siddeley, Austin, Aston-Martin, the new 14-h.p. Bean model, Bentley, the new Beverley-Barnes, Deemster, H.E., the new 6-cylinder 24-h.p. four-speed Lancaster, Sunbeam, Talbot-Darracq, Vauxhall, Warwick, and Waverley.

The first big effort by the French industry to introduce front wheel brakes was made five years ago. Much has been learnt by French automobile engineers in the interval. M. Henri Perrot's patents for diagonal application, and so forth, have been combined with those of Captain Hallot, the inventor of servo mechanisms; and a vast variety of engineering talent has been brought to bear on detail of problems of axle design, suspension, and so forth. The result is that, in regard to the application to standard cars, the development is in a satisfactory state as far as the French industry in general is concerned because its members have made many mistakes and learnt much. Further, the engineering talent brought to bear on the subject by Delage and Hispano-Suiza among firms that experiment by way of racing, has had very valuable results. M. Perrot, who is regarded as the man with most experience in the world on this subject—more than half a generation of it, considers American automobile engineers as a class to be at the same point to-day that French firms were in this respect five years ago. Like the French, he expects the Americans will have to spend quite a couple of years experimenting before they develop front wheel brakes which can be placed in the hands of the ordinary user with perfect safety. Nevertheless, some American manufacturers, including General Motors, are using certain of his patents under licence; this comment applies to the general, not to the individual, American case. French experience to date, which extends over 20,000 cars of various makes in the hands of private owners, has proved that some sort of servo mechanism is almost entirely absent from the designs used in this American designs. By contrast, in the designs used in this

country by the more responsible engineering houses about working the Perrot-Hallot patents under such firms as Bentley, Lancheester, Sunbeam, Vauxhall, but, as among the French makers, so among the others show extraordinary fertility of inventive re-creation dealing on wholly original lines with a number of auxiliary problems hitherto overlooked.

Of exhibits at the French Show there is nothing in and in respect of brake design, because undoubted leading automobile engineers have there solved practically all the problems necessary for safe use in the hands of the public. It is observable that this year that the leading makers are offering special axles, complete with front brakes, thus making it comparatively an easy matter for builders to apply these component units to their chassis. A point which will interest medical men is that the 10 Renault models are now fitted with front wheel brakes again, Cheneard-Walker produces one chassis on which there are brakes on the front wheels only, and none on the transmission. There have been some changes in regard to the front wheel brakes and also mechanism of the nominal 30/40-h.p. overhead valve 6-cylinder engine fitted in the last year. It has not been developed in detail in the extent that enables it to be standardized on a large scale.

The 15/20-h.p. Fiat has lightweight aluminium pistons with thin cast-iron skirts.

*Overhead Valve Engines on the Increase.*

A census of the valve systems used at the Paris Show reveals that there is no question about the overhead valve gaining in favour at the expense of the side-valve setting. It is observable that the French industry does not at over head valves for the more sake of falling in with an assumed vogue. Practically all the builders employing this system of valve gear do so to obtain greater economy and greater power; and, what is not invariably the case in this country, they achieve both. The 8-cylinder in-line engine tempers many manufacturers, including Holland-Pittman, who have employed the type for racing, and Cheneard-Walker, who produces one with 69.5 by 120 mm. bore and stroke measure-ments. The latest Chapuis-Dornier engine produced by that firm of specialists, whose products are fitted to many Continental vehicles, is a 4-cylinder unit with overhead valves and only 1,100 c.c.m. volume, the bore measure-ment being 59 mm. and the piston travel 100 mm. In nearly all designs the overhead valve gear is worked by push-rods and rockers enclosed in aluminium covers, this being the cheapest of the really effective forms of operation. The little Dornier power plant develops 20-h.p. on the Froude brake. Peugeot intro-duce a 10-h.p. model with 4-cylinder overhead valve engine, having detachable cylinder heads. De Dion-Bouton intro-duce a 20-h.p. 4-cylinder overhead valve engine chassis of 95 by 140 mm. cylinder bore and stroke, as does Moche-Schneider. On all the larger Renault models this firm's small car practice of placing the gearbox on the front end of the torque tube is exploited. Delage uses a 4-cylinder overhead valve engine for his new 12-h.p. car. The motor has a five-bearing crankshaft, forced lubrication, and the chassis a gearbox giving four speeds forward and, of course, brakes to all four wheels. Both Citroen models remain without any important changes. From Belgium there are sent Alimera and Metallurgique cars of the smaller middle size with brakes to all four wheels.

*A Cheap, Light, Silent, Covered Body.*

There are in the Salon various examples, including those standardized on the Delage and the Talbot-Darracq chassis, of the patent Weymann silent, cheap, lightweight, flexible, durable, easily cleaned, covered body schemes, the British rights of which were acquired by the Rotax Motor Accessorites, who have granted licences to Daimler, Rover, Sunbeam, and Talbot, among others; these firms will standardize this class of coachwork from the November London show onwards. I made a test of this type of bodywork on a large 40-h.p. Renault chassis, driven by the holder of the French aeroplane records, including sundry

the amount of destruction of the kidney. In large hydro-nephrosis the pelvis should be drained before injection, otherwise the injecting fluid becomes diluted. Pyelography is also the best method in the early diagnosis of kidney tumours. As, however, pyelography is the subject of a special paper by Mr. Ogier Ward, it is unnecessary for me to enter further into it.

Pneumoperitoneum is also of great help in the diagnosis of enlargements of the kidney. The importance of the prone position and lateral view between tumours and masses arising intraperitoneally has already been mentioned. In the antero-posterior view also the kidney outline is well seen, and there may be uniform enlargement with regular outline as in cases of compensatory hypertrophy and certain types of nephritis. The enlargement may be uniform, but with a smooth nodular outline, as in polycystic kidney or secondary carcinoma. One or other pole may be enlarged with the regular outline maintained, as in some cases of hypernephroma, or the enlargement may be irregular, as in sarcoma or other cases of hypernephroma.

Perirenal and colon inflation are other techniques which are of value in demonstrating variations in the outline of the kidney.

Having discussed the various methods at the disposal of the urologist and radiologist, and the differential diagnosis of the various shadows found in or about the urinary tract, one may now try to estimate the present-day value of  $x$  rays in the examination of this tract. This may be prefaced by stating that it should be constantly borne in mind that a uric acid stone will probably not cast any shadow to  $x$  rays, and although this is well known to radiologists it is perhaps not so frequently stated in their reports on negative cases as it might be. All other urinary stones show a definite shadow. Calcium oxalate stones show the densest shadow, then the phosphatic ones, and lastly the urates. There still occasionally seems to be a mistaken idea that the more rare cystin and xanthin calculi do not show, but even when almost pure they show quite a definite shadow, due to the sulphur element in their composition. It is probably not of much importance to attempt to diagnose the composition of the stone; it is of far greater value to be able to say with accuracy whether a stone is present or not, so far as  $x$  rays can go.

Another idea which seems to be prevalent is that urinary stones are rare in childhood. According to statistics this is not so, for the presence of stone in childhood and infancy is frequent. Some of these stones are known to have remained symptomless for some years, and it is likely that certain of the stones found in adults have had their beginnings in the early years of life.

All  $x$ -ray examinations of the urinary tract should be done so carefully that a negative opinion as regards stone may be, in the radiologist's mind and conscience at any rate, of real value—bearing in mind, of course, that such an opinion does not exclude a uric acid stone. Fortunately, however, uric acid stones rarely grow large enough to become of surgical importance.

With proper technique, if necessary with the help of one or more of the more elaborate technical methods, and with accurate diagnosis in collaboration with the urologist, there is no doubt that the value of  $x$  rays in urinary diagnosis, especially as regards the presence or absence of stone, is of the very highest importance. Most surgeons and urologists who have worked in conjunction with the radiologist and so made full use of  $x$  rays, will fully bear this out. There have been many mistakes in diagnosis by  $x$  rays, and there probably always will be some, as in every branch of medicine and surgery. It might, however, be pointed out that some of the shortcomings of  $x$  rays in this work would probably be avoided if only a closer relation existed between the clinician and radiologist. This lack is more noticeable in hospital than in private work. Radiology is indeed inseparably connected with urinary diagnosis, for although the eye, by the aid of many ingenious contrivances, has penetrated into many of the hidden parts of the body, yet it cannot possibly hope to penetrate everywhere as can  $x$  rays.

## GENERAL DISCUSSION.

Mr. R. OGIER WARD (St. Peter's Hospital, London) dealt with the subject of pyelography and cystography. He said that there was a general feeling, not so much amongst radiographers as amongst medical men in general, that the making of pyelograms involved a difficult, painful, and dangerous procedure. He was sure that radiographers who saw the work done would disagree with that idea. It was more correct to say that the work was tiresome to the radiographer, because pyelography required more time and trouble than a simple skiagram of the kidneys; it was tiresome to the surgeon, because he had to get a good deal of apparatus together; and it was tiresome to the patient, because a cystoscope had to be passed; but it was not really more than that. It should not be painful, as the modern cystoscope was a slender instrument, and if in difficult cases a cystoscope such as that which was used for children was employed the passage of it through the urethra produced very slight discomfort, particularly if a little novocain were introduced first. He considered that an anaesthetic should not be used, because one of the chief indications as to the filling up of the renal pelvis was that the patient complained of a discomfort in the loins, at which stage it was known that the dangerous limits were being reached. If the operation was done under an anaesthetic it was very difficult, unless one waited for the patient to come round, to fix the kidney sufficiently to obtain a satisfactory  $x$ -ray picture, and to wait for the patient to come round was rather tedious. There was no particular disadvantage in doing the operation under an anaesthetic if a special apparatus was used, such as Pannett had recently described, where the pressure of fluid which was passed into the renal pelvis could be very accurately regulated; but on the whole it was much better not to use an anaesthetic at all. He usually employed 20 per cent. sodium bromide warmed to about body temperature. He ran it in by joining a glass syringe on to the end of the ureteric catheter. It was important not to put on too great pressure; very serious accidents had happened in the past from that cause, particularly when an attempt had been made to perform the operation under anaesthesia. Pyelography had many obvious uses in urinary surgery, but perhaps its most important value was that it gave information of the condition of the kidney and its pelvis which could not be obtained by any other means. Mr. Ogier Ward, in conclusion, exhibited slides illustrating the value of pyelography.

Dr. L. A. ROWDEN (Leeds) drew attention to one point in the diagnosis of renal calculus—namely, the importance of screen examination combined with palpation. He considered that not sufficient attention had been drawn to this in the past. In the corresponding Section at the Annual Meeting of the Association in London in 1910 he drew attention to this matter.<sup>1</sup> Speaking of the radiographic prints which were hanging in the room illustrating the urinary tract, Dr. Rowden said that he was certain he could have seen on screen examination, with proper technique, every shadow that he saw on those prints. That was rather an astounding statement to make, but he had been careful to qualify it by the words "with proper technique." First of all, it was necessary that the tube should be a Coolidge tube, so that it was possible at any moment to alter the penetrating quality of the rays to suit the case under examination. Secondly, it was absolutely essential that the tube should be brought as close to the patient as possible without sparking on to the patient. Thirdly, the eyes of the observer must be properly prepared for the examination. The examination was conducted always with the patient lying on the couch in a horizontal position. The diaphragm was not a mechanical one, but a fixed one, less in size than the area of a postage stamp, and by preference it should be tubular. The box which contained the tube should have free movement up and down and crosswise, but be desired particularly to emphasize the fact that the tube should be as close to the patient as possible. By that means it was astonishing what could be seen on the screen when the

SATURDAY, OCTOBER 13TH, 1933.

## THE RENEWAL OF THE INSURANCE MEDICAL SERVICE.

Not very far short of one-third of the total population of Great Britain is provided with its ordinary medical attendance and treatment through the National Health Insurance system. By no means all of these persons need the provision which the State has made for them; some never take advantage of it at all. Many insured persons are well paid weekly wage-earners; many others are members or dependants of well-to-do families. Most of these would receive the medical attention they need through the ordinary method of private practice if the insurance system were not in existence. Nevertheless, it is to be reckoned a national advantage that the remainder, constituting the great majority of the insured population, should have this help in obtaining medical attention, and it is an asset to the profession as a whole that this work should be provided for it with the certainty of regular payment therefor quarter by quarter.

The State, being responsible for the establishment and administration of this system, and paying fully two-thirds of the cost thereof, quite properly makes provision for defining the range of service which doctors shall be expected to give in connexion therewith, and the general conditions under which this shall be given, and for securing that the duties undertaken shall be carried out with reasonable care and efficiency. So long as there is no interference between doctor and patient as to the actual advice and treatment given, and so long as any penalty falls only upon those who have wantonly broken or failed to perform a contract into which they have chosen to enter, regulations and arrangements must be accepted as necessary, inconvenient, though unfortunately rules have a tendency to become more complicated and helpful supervision to degenerate into unhelpful inspection. There are many general practitioners who do not care to enter into any contract at all; these stand apart from the service. There are others who do not join the service because they feel a sufficiently strong dislike to some particular conditions of the actual contract which have to be accepted. The essential things in this connexion are that the profession shall have its full weight in deciding the terms and conditions, and that those who are chosen to conduct negotiations on its behalf shall be fully aware of professional opinion and sympathetic towards the traditions of the profession.

The community, however, should, and presumably does, require from a service like this something more than the mere treatment of individual persons when they are ill. To alleviate suffering and to cure sick persons is doubtless a national as well as an individual advantage; but it may be of even greater importance in the long run to use preventive methods by giving advice and instruction with regard to personal, domestic, and workshop hygiene, to use the unrivalled opportunities which such a service provides for research into the beginnings of disease and other cognate problems, and to gather and supply any information which may reasonably be

required from time to time by local or central health authorities. Practitioners who enter the service undertake important duties to the State as well as to their individual patients, and there is no reason why there should be any clashing between the two functions—at any rate to a greater extent than is sometimes inevitable in any kind of medical practice. Such a service is obviously an essential basis for wider things in two directions. It is the fundamental benefit upon which any other benefits of the insurance scheme depend. Without it, sickness benefit and disablement benefit in the form of cash payments, maternity benefit, and any other additional benefits, such as dental, ophthalmic, nursing, or convalescent, could not be economically given or wisely used. Hence arises the extreme importance of medical certification for the success of the scheme. The general practitioner medical service, too, is the foundation on which any further expansion or extension of consultation or specialized work, whether for diagnostic or therapeutic or research purposes, must be built. Such a development of the service, involving the co-operation of hospital staff, pathologists, radiographers, and other members of the profession, has long been fore-shadowed. But without an adequate and thoroughly efficient general practitioner service as the first stage, these developments would fall of half their usefulness, and would tend to become a wasteful extravagance.

It might be supposed that the enormous importance of this service, so extensive, so powerful for national health purposes, so essential for the safeguarding of other expenditure, and so fundamental for future development, would be obvious to any Minister of Health. Yet in the official attitude towards the present negotiations as to the terms of service for insurance practitioners after the end of this year there has been so far no evidence of wide outlook, of real vision, or of statesmanlike grasp. It is obvious that if the insurance medical service is to be useful to the community and worthy of the nation, it must make its appeal to the great body of the profession, as will lead to a wide distribution of insured persons among doctors of their own choice who will have time to do good work without distinction between one class of patients and another. To do that it must enlist and retain the help of successful and experienced practitioners, as well as those who are just entering the profession, and those who are constrained to remain in the service by sheer economic need. The whole profession will support the Insurance Acts Committee in saying that the level of remuneration should be directed to this end, and it is to be expected that public opinion will also declare that it is not sufficient for the Minister merely to ask himself, "What is the lowest fee for which I can get a number of doctors to treat insured persons when they are ill, and to give the necessary certificates?" What is the reason for this shortsightedness? They are mainly grouped in approved societies. The 14,000,000 insured persons are compelled so to group themselves if they wish to reap the proper advantage from the insurance scheme, but only a very small fraction of them take any interest whatever in the constitution or administration, or even in the rules, of the society to which they belong. The great majority, having joined a society, have no further real connexion therewith; many even do not know which society they are members of. Let the officials of these societies technically "represent" insured persons; they administer all benefits other than medical benefit, they

that in Dr. Rowden's hands this had given most valuable results; he could not feel, however, that it should be adopted as a routine, but rather as a procedure to be followed after the films had been developed, and some doubtful point remained to be cleared up. He could not agree that the majority of gall stones as seen in films of patients showed a homogeneous shadow; in his experience there was usually a denser periphery producing a somewhat ring-like appearance. He was very pleased to hear Mr. Ogier Ward praising pyelography so highly; it was gratifying also to hear the same speaker advocate lateral views, which some others had spoken of rather disparagingly. As Mr. Ogier Ward had pointed out, lateral views would often avoid the necessity of making a pyelogram. He entirely agreed with the remarks of Dr. Metcalfe and Dr. Batten on the advantages of perirenal injection and the Potter-Bucky diaphragm.

### DEMONSTRATION.

#### *The Silhouette Radiograph.*

In the Pathological Museum in the course of the meeting Mr. A. P. BERTWISTLE (Resident Surgical Officer, General Infirmary, Leeds) gave a demonstration of a simple method which he had devised for the more ready interpretation of prints from x-ray negatives. Owing to the inability of printing papers, especially bromide, to indicate a structure whose density is so slight as that of flesh, x-ray prints commonly show no trace of flesh outline, although such outline may be clearly indicated on the negative. To bring out the skin contour without the sacrifice of the definition of the bone is a matter of some difficulty. The demonstrator has adopted the simple expedient of scratching the skin outline on the negative—in the case of a film, scratching both sides—with a pin before printing. The result in the print is a black line corresponding to the contour of the part. The background in the print is then filled in with Indian ink, thus completing a silhouette radiograph.

The silhouette radiograph has for its object the correlation of clinical findings with those of x-rays. It is a shadow of flesh and bone, not of bone only, as in the ordinary printed radiograph. After some experience of silhouette radiographs, Mr. Bertwistle said that one could very well predict from the surface appearance what the radiographic findings would be. Certain deformations became immediately indicative of conditions of bone. The bulbous finger-tip, for example, often revealed a periosteal whitlow, and a spindle finger indicated tuberculous dactylitis, both alterations being typical. The "wave" deformity of the arm meant a "greenstick" fracture of the radius and ulna. An injury to the knee, followed by loss of extension and a transverse groove over the site of the patella, made it probable that there was a fracture of bone. Similarly in an injured hand which was radially deviated and displaced backwards in the "dinner-fork" position, it was easy to visualize an impacted fracture of the radius, with marked displacement of the lower end. One of the points in the diagnosis of tuberculosis of bone was the extreme wasting of the surrounding muscles which accompanied the condition. Rachitic and malignant diseases were not accompanied by such wasting, nor was osteomyelitis, in which condition irregularities due to sinuses were frequently apparent. The relation of swellings to bony changes was readily demonstrated by this method.

An important use of the silhouette radiograph was its indication of the position in which the limb was x-rayed. It gave the observer his bearings. The demonstrator suggested that the scratching of the negative in the manner he had indicated, before the print was made and dispatched, would greatly increase the value of the print to the practitioner who asked for it. Again, from the point of view of the publisher, the addition of the black background enhanced the bony definition and gave the picture a more finished appearance. It enabled him to print several illustrations of different density on the same page without producing an inartistic effect. Moreover, the clean-cut silhouette was easier to obtain and often revealed more than the mediocre photograph. For example, an encephalocele so treated indicated both the tumour and the defect in the skull. The geography of sinuses was readily ascer-

tained by this method; a sinus into which a probe had been passed or bismuth injected would show the relation of its terminations to the skin. A foreign body, instead of appearing in a state of vague suspension, would assume a reasonable situation. Altogether, the addition of the silhouette imparted reality to the radiograph, a factor which would assist in diagnosis and treatment.

The demonstrator expressed his acknowledgements to Dr. L. A. Rowden of Leeds for his interest in the work, and to Dr. Scargill and the radiographic staff of the General Infirmary for the preparation of material.

### SECTION OF OPHTHALMOLOGY.

Sir JOHN H. PARSONS, C.B.E., D.Sc., F.R.S., F.R.C.S.,  
President.

### DISCUSSION ON

### OPHTHALMOLOGY IN ITS RELATION TO THE NAVY, ARMY, AND AIR FORCE.

#### OPENING PAPERS.

I.—AIR COMMODORE DAVID MUNRO, C.I.E.,  
R.A.F.M.S.

#### SOME EYE PROBLEMS SPECIAL TO THE SERVICES, WITH PARTICULAR REFERENCE TO FLYING.

WITH the advent of flying the functions performed by the eyes in co-ordinative movements have assumed particular importance. To the cricketer whose eye is not "in" nothing worse than a "duck" can happen; to the aviator it may mean anything from a bad landing to a fatal "crash." A single-seater service aeroplane approaches the ground to land at a high speed, and to perform the evolutions required in landing the pilot has to alter the course of the machine from the gliding angle at which it is descending to a horizontal position—what is called "flattening out." He has to judge the exact moment at which to "flatten out," and the judgement is dependent on his estimation of the pace of his machine in relation to its distance from the ground. If he flattens out too high up he will lose flying speed before he reaches the ground, and gravity—the vertical component of the parallelogram of forces which is producing his diagonal glide—will take the upper hand. The machine then will fall vertically in the latter part of its course. If he neglects to flatten out till too late he will fly into the ground at an angle.

This correct estimation of pace and distance seems to depend on "eye" exactly as in games the estimation of pace and distance in hitting a ball depends on "eye." What does "eye" in this connexion mean? Doubtless in the act of landing an aeroplane, just as in other complicated co-ordinative acts, the brain takes note of afferent stimuli other than those which it gets through the eye.

Tactile sensation from the skin through the pressure of the wind on the face assists the pilot for an estimation of pace, also pressure of body against seat of machine. Muscular sense also is of the highest importance; as in riding, "hands" make all the difference. The sound of the engine tells its tale to the man who knows, yet in the main it is through the eye that the brain gets information and makes its controlling judgement.

Briefly we affirm that for a pilot it is necessary that the whole optic tract should be functioning normally. We lay stress on good visual acuity in both eyes, for two emmetropic eyes are more likely to work together than two eyes of unequal refraction; but we lay most stress on the co-ordinative machinery by means of which accurate binocular vision is automatized. Inequality in function between the two eyes we regard as dangerous. Hence I venture to say that while there may be many good players of ball games who have indifferent visual acuity there are few if any who have any marked degree of inequality in functions between the two eyes.

The essentials for good binocular vision would seem to be:

1. Correct co-ordinative movements of the eyeballs as performed by the extrinsic ocular muscles.
2. Unison in the associated movements of convergence and accommodation as performed by both extrinsic and intrinsic muscles.

"It is due to intelligent use of the human factor through-  
out the whole machinery of government—in factories and  
workshops under the Home Office, schools under the Board  
of Education, ships under the Board of Trade, through-  
out the Services and Colonies and Dominions, in fact in  
every department of local or national government, as well  
as in works, because of former deficiencies, have been looked  
on as works of sanitation—water supply, sewerage—or  
housing or hospitals, which only go to repair the failure  
of the health factor throughout national life under all  
departments of government. But the two activating prin-  
ciples of public health are research (under the Privy  
Council) and public enlightenment, which surely should  
come under the Board of Education." Dr. Freeman-  
Smith went on to say that the understanding and continuous decline  
in infant mortality since 1900 was shown at the Portsmouth  
meeting of the British Medical Association to be mainly  
due to public enlightenment. "The main value to public  
health of medical officers of health," he continued, "is as  
a centre of public enlightenment, and it is as well that  
they should also be, as they often are, the school medical  
officers. The health problem of the medical services under  
the Ministry of Health would be solved by fusion of the two  
departments." In conclusion Dr. Freeman-Smith said that  
while he was aware that some would wait for a complete  
rearrangement of our whole system of local government by Royal  
Commission, he himself believed that it would be wise  
and useful to begin by the regrouping he proposed.  
His suggestion has been interpreted as amounting to  
the abolition of the Ministry of Health. It was so taken  
by the Prime Minister, who, in his reply, spoke of  
the proposal as one for "redistributing amongst other  
existing departments the functions now assigned to the  
Ministry of Health." To such a proposal Mr. Baldwin  
objected on general grounds. The problem, he said, was  
policy on a *provisory* generalization might be the reverse of  
successful. In the sphere of business, he continued, it is  
never a safe rule to assume that whatever is logical is also  
expedient. So important a problem of administration, he  
should be closely studied from every angle (in-  
cluding choice of a suitable moment) before a final decision  
is taken to tear up everything by the roots or to leave  
everything alone." His considered conclusion is that  
"any attempt at the present moment at concentration on  
a big scale would be premature and inappropriate and might  
reasonably lead to the loss of far more money than, on any  
reasonable assumption, it might be expected to save, as well  
as to decrease of efficiency." In reply to the Prime  
Minister's letter Dr. Freeman-Smith did not specifically repu-  
diate the suggestion that his proposal would amount to  
the disappearance of the Ministry of Health by the distri-  
bution of its duties to other Government departments.  
We can see many advantages in bringing the school health  
service directly under the Ministry of Health, but on the  
other hand would deploy any change which would result in  
relegating the central administration of public health once  
more to a subordinate position. In saying this we believe  
we express the opinion of the medical profession as a whole.  
We cannot believe that the abolition of the Ministry of  
Health as an independent Government department would  
be approved by the profession or be to the advantage of the

public.

[illegible]

THE JAPANESE PATHOLOGICAL SOCIETY.  
The Japanese Pathological Society is a very active body, and the last volume of its transactions (vol. xiii) contains several contributions of interest. In it Suzuki describes experiments which he considers throw light on the nature of nephrosis (chronic parenchymatous nephritis).

considered good. An exophoric case may give at first an esophoric displacement owing to overcompensation, but as fatigue sets in the red image appears to swing through normal to the exophoric position. Hyperphoria or hypophoria combined with exophoria or esophoria exaggerates any liability to bad landings. Tendency to neglect one or other eye or each alternately is a marked and frequent feature in bad landers.

**Bishop Harman's Movable Diaphragm Test.\***—This test has proved invaluable as a check on the others above mentioned. It has been found that a reading of 3 is a "border-line" one and that 5 is bad. First-class landers usually give a reading below zero; average landers, zero to 2; doubtful landers, 2 to 3; whilst those giving readings of 3 to 5 or more fall into the category of bad landers. Most of the individuals who landed badly had normal visual acuity and little if any error of refraction.

I wish to emphasize one point—namely, that I am considering the subject in terms of conditions "in the air," and I would ask readers to keep an open mind and not judge my remarks too critically by standards which operate "on the ground." I ask this for these reasons:

1. From birth upwards all our judgements of distance have been made with one known quantity—our contact with the ground. When, however, the aeroplane wheels leave the ground the pilot is in space, and this previously known quantity is immediately lost. What is more, before he can successfully land his machine he must make as correct an estimate as possible of the distance he is from the ground.

2. From the air all verticals are foreshortened and the known size of objects therefore varied from those which we have learnt as normal on the ground.

3. The action of centrifugal force on ocular muscle balance during turns, spins, loops, etc., has to be taken into consideration. If flying in a tight spiral looking in the direction of the aeroplane's course, or towards the centre of the "funnel" down which one may be travelling, no unpleasant effects will be felt; but if one looks outwards—that is, away from the centre rotation—the pain of having one's eyes apparently pulled out of the head is agonizing and a more comfortable position will be rapidly taken up. On coming out of a spin the horizon will appear to be going round in the reverse direction, and if the action has been excessive the pilot may be under the impression that he is not yet out of the spin, and make some further adjustment which results in his resuming spinning in the opposite direction with possible damage to himself or even fatal results. If a pilot has some tendency to imbalance then it would seem that rotation will be likely (by putting undue strain on the affected pair) to increase such tendency and to make his judgement faulty.

In conclusion I would like to make the following observations: The independent investigation of Group Captain Plack, made on Air Ministry instructions in the war, showed 80 per cent. of successes from eye training, and that by only treating suitable cases this percentage has improved since that time. Not only is greater proficiency in landing obtained, but also in game shooting and all fast ball games as the patients attest. The course only occupies a short time daily for three to five weeks.

The Air Ministry after careful investigation of results now sanctions the training of service officers who develop the defect, and bad visual judgement, even though visual acuity is up to standard, is now a definite cause of rejection for candidates. Lastly, instructors are sufficiently satisfied with the results to apply at once for an opinion where a pupil shows signs of inability to land.

#### GENERAL DISCUSSION.

Major-General Sir WILLIAM MACPHERSON, A.M.S., said that he responded with great diffidence to the President's invitation to take part in the discussion. The army had nothing like the scientific accuracy and ophthalmological researches of the flying services. In fact, the work of the flying services had given an entirely new aspect to the ophthalmological problems of the services. For a long time the tests in the army were by dots representing at a given distance the bull's-eye of a target at 600 yards. This was eventually replaced by the test types; but there was no differentiation between tests for visual acuity and errors of refraction. It was only the latter that was tested. But some years ago the Adjutant-General considered that artillery officers should have absolutely normal vision, and should not need to use glasses. Now this showed a wrong idea of ophthalmological conditions, because a myope with

perfect visual acuity was really more valuable in long-range work of artillery than a man with a less degree of visual acuity but with little defects in refraction, because he was bound to use field glasses for his observations. During the war the fighting services were given spectacles. The chief difficulty with the infantry was that spectacles got dimmed by rain and mist, or got broken. One curious effect of the war was that spectacles had to be issued to the presbyopic.

Mr. RANSOM PICKARD (Exeter) said that during the months of February to April, 1915, he examined a number of men in a regular division in France. It became obvious in the first two months that those who had visual troubles were mostly those who had more than 1.5 H; and that difficulty in seeing at night existed much more in these than in other men examined. In the next two months, with an equal number with refraction above 1.5 H, there were no complaints of night-blindness—when the nights were shorter. It was obvious that the difficulty at night was one of muscular strain in most cases. The practical issue was whether men having more than 1.5 H could, under present recruiting conditions, be excluded from the army.

Major E. B. SPAETH (U.S.A. Army) described some cases of plastic repair of the lids and the sockets by means of two methods, the first the presentation of the use of pedicle flaps for the simultaneous repair of both of the lids, and the fundus of the orbit also, should that be necessary; and the second a series of photographs showing ophthalmic correction of various defects and deformities according to the method of epithelial inlays of Gillies.

Mr. M. W. B. OLIVER (London) did not agree altogether with the methods of Major Spaeth, and especially criticized the forehead flaps. He discussed the question of glasses, and suggested that no man should be considered fit whose vision was not sufficiently good without, as glasses were frequently lost in action. He also discussed the question of night-blindness, and some methods of protection from missiles.

Mr. N. BISHOP HARMAN (London) said that the work that had been presented to the Section by Wing Commander Clements, R.A.F.M.S., was a most valuable contribution to their knowledge of the causes and effect of defective muscle balance. There were few conditions in civil life where such severe and sudden stresses occurred as those found in flying. But in the long continuance of ill health, especially those due to disorders of the alimentary tract, where there were at one and the same time defective nutrition and toxic absorption, there were to be found conditions which brought about ocular states very much akin to those set up by the more severe stresses. He illustrated this condition by cases of hyperphoria becoming troublesome for the first time in such states of ill health, and the immense comfort which could be secured for the patient by the discovery of these defects of muscle balance and their correction. Relief to these patients was the more important since their ill health often left them few relaxations beyond reading, and the ocular defect made reading difficult, even distressing.

Mr. E. E. MADDOX (Bournemouth) said that provided both eyes had good visual acuity, and the ocular balance and motor apparatus were good, the existence of a master eye was not incompatible with excellent orientation, and of this fact his old teacher, Dr. Argyll Robertson, was a good illustration, for although one eye was perfectly normal, and a complete master, while the other was astigmatic, he was as true an archer as to be included in the King's Body Guard for Scotland, and was esteemed by many to be the best beautiful operator in Britain. In the selection of candidates for aviation, Mr. Maddox suggested taking account of the nervous system as a whole, since defective ocular balance was so often accompanied by slight nerve defects elsewhere. In effecting a landing, coolness and collectedness were necessary to give the motor apparatus its proper training; there must be an absence of

\* For description of this test see *Ophthalmological Society's Transactions*, vol. XXX, p. 55.

to other investigators, and 14 were grants to scientific workers to enable them to employ laboratory assistants or to purchase equipment; the total expenditure on these grants was £50,000. The total expenditure of the Committee during the financial year was £497,549, of which £264,483 came directly from the Exchequer, while £233,066 represents fees for tests and special investigations for out-side bodies, and repayments from the Service departments.

#### DETACHMENT OF THE RETINA.

The treatment of detachment of the retina is so unsatisfactory that it seems worth while to record any suggestions, and we therefore give particulars of an operation recently devised by M. Felix Lagrange and described by him in *Gluconic et Hypotonie*, published in Paris last year. The operation, to which the term "colmatage" is applied, is performed under cocaine anaesthesia. With deeply into the sclerotic, round one half of the limbus; these points are arranged in three rows; it is not necessary to dissect up a flap of conjunctiva first. The burning point is laid on, for the first row, just beyond the limbus, and a half-circle of dots, usually about ten in number, is burnt; the second row is placed a little further back, and the last row further back still; in this way half the circle of the limbus is surrounded, and the other half may be completed at another sitting if necessary. We have heard of one case of retinal detachment treated here in this way; the immediate result was brilliant, for very useful vision was regained; after a year, however, the man returned with a recurrence, and this has resisted all treatment. The theory of Lagrange's operation is that the burning induces sclerosis of the tissue surrounding the detachment of the eye, and that in consequence the tension is raised in eyes in which the tension is low and in which this operation it would be necessary to see that the retina was uniform and that the vitreous was in a healthy state; with a torn retina and with an unduly fluid vitreous, as evidenced by a gross amount of freely movable opacities, any operation could be undertaken only with considerable hesitation.

#### THE LONDON SCHOOL OF DERMATOLOGY.

We announced briefly in our last issue that in order to further the study and teaching of dermatology in London a comprehensive scheme of co-operation had just been completed in connection with St. John's Hospital for Diseases of the Skin. For many years past it has been recognized that dermatology in the metropolis has suffered from want of concentration and combined effort. Each of the London general hospitals has its dermatological department, for which as a rule one physician takes responsibility. The new scheme is the outcome of negotiations that have been proceeding during the last few months between the medical staff of St. John's Hospital and a number of leading London dermatologists, with a view to developing further the existing facilities at St. John's, and combining to establish a central school for the study of clinical dermatology and cutaneous pathology. The hospital, situated centrally in Leicester Square, presents ample clinical opportunities and possesses considerable facilities for concentrated teaching. Under the new scheme additional members have been appointed to the staff of St. John's Hospital. Thus Sir Malcolm Morris and Dr. J. H. Stiles have joined the consulting staff, and will each have a seat on the board of management; Dr. Wilfrid Fox and Dr. Henry MacCormac have been appointed to the active staff; Dr. J. M. H. MacLeod becomes director of the pathological department.

#### THE MEASUREMENT OF PROGRESS IN PUBLIC HEALTH.

SIR ARTHUR NEWSHAM delivered the William Farr lecture on October 4th. His subject was "The measurement of progress in public health." The first part of the lecture was devoted to an examination of the work of William Farr, who was appointed compiler of statistics in the General Register Office in 1837, and for forty years subsequently devised the methods and supervised the actual compilation of national mortality statistics. Farr's guiding principles were that the evil factors at work in the community, making for injury to life and health, must first be measured, that their relative incidence in respect of age, sex, social condition, and so forth should next be ascertained, and that finally public attention should be drawn by every possible means to the factors thus ascertained. Most vital statistics consisted of aggregates in which it could not be ensured that one causal factor was isolated from others which were in action at the same time. Thus infant mortality was directly related to poverty, but extreme poverty or pro-perity might both be

and the venereal diseases department will be in the charge of Dr. Wilfrid Fox. The other feature of the scheme is working in close touch with the medical committee of the hospital, will be in the hands of a larger body, consisting of the medical staff (both consulting and active) of St. John's Hospital, together with the physicians in charge of the dermatological departments of the twelve metropolitan hospitals with medical schools attached. Under the auspices of the school the Christchurch lectures, constituting a systematic elementary course in dermatology, will be given on Thursdays at 5 p.m. from October to March, by the honorary medical staff of St. John's Hospital. Special lectures and demonstrations will be given on Tuesdays at 5 p.m. by the physicians in charge of the dermatological departments of the London teaching hospitals. Instruction will also be given daily in the out-patient department, and it is proposed to make arrangements for classes or individual instruction to be given in the pathological department. Further information on all these matters may be obtained from the Dean, Dr M. G. Hanway.

#### THE COUNCIL DINNER.

The Council of the British Medical Association is holding its second Annual Dinner on Wednesday, October 24th, at the Hotel Victoria, Northumberland Avenue, at 7 for 7.30 p.m. The chief guest will be Sir Dawson Williams, and the dinner will be made the occasion of celebrating his completion of twenty-five years as Editor of the *British Medical Journal*. Among those who have accepted the invitation, issued in the name of the Chairman and members of Council, are the Minister of Health, the President of the Royal College of Surgeons of England, Sir George Newman, Sir Arthur Robinson, the heads of the Medical Departments of the Services, and the newly appointed Medical Adviser to the India Office (Major-General J. B. Smith). The dinner last year was very successful, and there was not enough room for all who wished to attend; a larger hall has been secured for this occasion. Members may bring guests, and ladies will be welcomed. Applications for the remaining tickets should be made at once to Mr. L. Ferris-Scott, Financial Secretary and Business Manager, 429, Strand, W.C.2. The price is 10s. 6d., exclusive of wine.

many unsolved problems of vision in relation to the requirements of the combatant services which have been brought before it. The meeting is convinced that efficiency and economy can only be obtained through the solution of these problems.

Mr. A. C. ROPER (Exeter), in supporting the resolution, said that some practical result should ensue from the important discussion on ophthalmology in the services, and that could be best attained by pressing upon the Government the importance and absolute necessity, in the interests of the public weal, of instituting research on these vital points.

The resolution was carried unanimously.

## VISION IN NAVAL GUN-LAYERS.

BY

SURGEON COMMANDER W. K. D. BRETON, R.N.

THE efficiency of a gun-layer or range-taker must very largely depend on his degree of visual acuity, and it seems to me that in such highly specialized ratings existing convention is hardly stringent enough. When we say that an individual can read normal vision, or 6/6, we infer that he can recognize, as disparate, objects which subtend at the nodal point of the eye an angle of approximately 1 minute of arc. It has long been recognized that many can read 6/5 or even 6/4 and better, and in doing so define for themselves a visual angle that is very much smaller than convention demands. Hartridge and Owen in 1922 pointed out that with a single black line on a wide white field, where the conditions of simultaneous contrast are perhaps ideal, the width of the black line may subtend an angle of as small as 3.1 seconds of arc before visibility ceases. It is therefore very obvious, without going into further detail, that between existing convention and experimental result a wide hiatus exists. I have made a point of refracting, under a mydriatic, all men who failed to read 6/4 easily, and it has been my experience that in practically every case a small cylindrical error, often with a certain obliquity of axis, has been present.

During the last six or eight months I have examined 186 ratings, qualifying or requalifying for higher rating. Of these 114, or 61.3 per cent., read 6/4 in each eye, 11, or 6 per cent., read 6/5 in each eye, 9, or 5.3 per cent., read 6/6 in each eye, whilst the remainder showed varying degrees of defective vision. It must, of course, be emphasized that one is dealing with picked men in the third and fourth decades of life, and that, as executive ratings, they had all passed an initial test demanding 6/6 in each eye. To quote one example from our latest Admiralty Order on the subject, gun-layers may be passed for initial test if they can read 6/9 in each eye tested separately, and if any spherical or cylindrical error can be corrected by, at most, a 1 plus or minus spherical or cylindrical lens, or combination of these lenses. Requalifying tests, every two and a half years, are similar, but permit 6/12 in each eye. My problems then are: (1) The practical significance of small cylindrical errors which permit a man to read 6/6 or perhaps 6/5 partly, but no more. (2) Whether it is justifiable to assume that every healthy emmetrope should easily read 6/4. (3) Whether considerations along the lines I have indicated justify more stringent regulations in assessment. (4) Whether it is definitely proven or not that, apart from gross disease, as diabetes, there is evidence to show that an initially determined axial error may change from time to time.

**Stereoscopy.**—A wide controversy has for long existed as to the merits of the stereoscopic range-finder against the coincidence or monocular instrument; the latter, of course, depends for its efficient use entirely on monocular visual acuity. As far as I know a convention, as the visual angle, does not exist in estimating stereoscopic efficiency. Measurements are usually made and recorded in terms of parallactic change, and triangulation determined by taking the I.O.D. as the common base and the distant objects as the apices. Ability to judge distance, after eliminating all monocular potentials, is recorded in circular measure. Various figures have been recorded from time to time which show a mean stereoscopic accuracy of 8.2 seconds. In my

own experiments during 1921 a mean accuracy of 4 seconds was frequently obtained. It must be observed, however, that such tests have been carried out under laboratory conditions, and there is no evidence to suggest how soon inefficiency and asthenopia from fatigue will supervene. My problems therefore are: (1) To find a convention that may be defined as normal stereoscopic vision. (2) To ascertain whether an initial high standard of stereoscopic efficiency will rapidly tend to wane either from fatigue or stress of circumstance.

**Muscle Balance.**—Present regulations disqualify where any imbalance exists exceeding 2 degrees prism, except in the case of stereoscopic range-takers where orthophoria is demanded. As far as inco-ordination in the vertical meridians is concerned, I am inclined to reject any candidate for higher rating, however small the imbalance. My problems are: (1) To what degree deviations in the horizontal meridian may be permitted in monocular work, as in coincidence range-finding, laying, etc. (2) The prognosis and treatment of moderate deviations in the horizontal meridian. A case recently came under my observation (a candidate for gun-laying—that is, monocular work) who read 6/4 in each eye, but had 9 degrees prism of exophoria. According to regulations he is unfit. Should this be so?

**Colour Vision.**—I have found few subjects more difficult to fathom than the various theories of colour vision. In any service we are naturally more concerned with practical tests than theory. I think I am right in assuming that the older tests—as Holmgren's wools, coloured beads, etc.—are obsolete and untrustworthy. I am at present using a series of test cards devised by Edridge-Green which appear to me an effective method of rapidly categorizing colour defects or those showing a shortening at either end of the spectrum. My problems are: (1) Whether any other test of greater practical value exists. (2) Whether a tetrachromic (that is, an individual who can only distinguish four spectral colours—red, yellow, green, violet) may be considered normal for all practical purposes; in my series of 186 I had three dichromics who could apparently only distinguish the spectral ends red and violet.

## NAVAL LIGHTING.

BY

SURGEON CAPTAIN R. J. E. HANSON, R.N.V.R.

THE senior service is keeping well abreast of recent work in ophthalmology, for no section of the community is more exposed to dazzle or more susceptible to the ill effect of faulty illumination in the confined spaces of modern naval craft.

A Naval Code of Lighting (see below) is now available for the guidance of those engaged in illumination. A discussion on the matter of this code would be helpful to the service and much appreciated.

Special attention has been given to certain inquiries from the hydrographic department of the Admiralty. In the tropics dazzle is a serious problem in boat work surveying. To eliminate this factor a pale green-tinted matte surface for drawing paper has been designed, this surface to be held, when possible, so that sunlight is not directly reflected into the observer's eyes.

The linear markings and notation on the survey staves have been revised, in conjunction with Captain Douglas, R.N., Assistant Hydrographer—so that the relative height and width of the foveal field is maintained when reading off lines and figures through glasses. Experimental work has been done at Whale Island, also in the submarine department, and at Kew Physical Institute, respecting visual and postural fatigue in the use of periscopes and gun-sighting telescopes, etc. As the "orbital cone" of muscles effects the finer co-ordinate movements of the eyes, so the "spinal polygon" (small recti capitis muscles) are in co-ordination with the orbital cone, and effect, by their action, an increase in range of vision field without movement of the trunk.

To allow these two sets of muscles unharassed action (absence of fatigue and strain) it is necessary to give rest position to the large head-neck-trunk muscle groups. This has been achieved by use of an alternating head rest and

INSANITY AND MENTAL DEFICIENCY.

usual report of the Board of Control for 1922, to a brief reference was made in our issue of 29th (p. 573), again brings to our notice the connection with the insane and mental defectives, as revealed in the report as to the incidence of these are serious and cannot lightly be ignored by the

*Increase of Insane Persons under Treatment.*

and of 1922 there were no fewer than 106,247 persons in England and Wales, and the total expenditure of the county and borough asylums, and maintenance, supervision, and treatment of patients amounted to £7,658,823. These figures do not the numbers or cost of the certified mental defectives in insane and defectives in Poor Law institutions. In admissions during last year were 23,125, the number the Board has ever recorded with the solitary of 1914; the average annual increase in the resident in county and borough mental hospitals in the years 1920-22 was 3,402 as compared with an increase of 2,095 for the ten years 1911-1920. The increase in the numbers of persons is somewhat disquieting, as it suggests a tendency to increase out of proportion to an of the population. The admission rates, however, are not marked fluctuations in the past, and it is to read in the report that, while the ratio of males to females in mental hospitals is rapidly increasing, it is due, of course, to accumulation, as the rate is more numerous than the discharges and the death rate has considerably diminished in hospitals and will no doubt continue to do so as the of comfort, treatment, and nursing is raised, and rd points out that, should the large rate of increase numbers resident in mental hospitals continue, the would be available at present and in the immediate future sufficient only for the needs of the next three years.

*The Outlook.*

thus evident that, unless we are able to diminish the of insanity or effect more recoveries, the segregation of an increasing number of certified cases will be a pessimistic attitude in regard to the problem to be quite unjustifiable. Psychiatry is full of promise. A resistive, degraded, hostile, and deluded insane for ten years, may completely recover and well; a paranoiac to whom a hopeless prognosis has assigned may lose his delusions and resume his place in the world—surer than he has ever been. In such cases unknown changes have occurred in the organism which in cure, and it is obviously the task of medicine to those mysterious processes of Nature which both cure and disease. The first essential for the prevention of insanity is more knowledge of its causes, and the development of research in mental hospitals. It includes a record of work which has been undertaken during the year, as well as a number of proposals for the future research centres and laboratories. The importance of Research Work.

no increasing burden of insanity is to be diminished, it is research essential, but early treatment as well. It is sufficient evidence to justify the view that a certain

proportion of cases of mental disorder can be prevented from drifting into chronic insanity if remedial measures are taken at an early stage of the illness. The main problem at the moment is how to get incipient cases under medical treatment, and some means must be found of inducing patients and their friends to invoke curative treatment in time. The difficulty is largely a legal one, and it is most desirable, as we have frequently urged in these columns, that those legal restrictions which at present stand in the way of early treatment of mental disorder may speedily be removed by appropriate legislation.

*Out-patient Clinics.*

Apart from this, the Board of Control strongly advocates the creation of out-patient clinics in connexion with general hospitals for the treatment of mental cases. They point out in their report that there is a natural reluctance on the part of most people to undergo institutional treatment anywhere, and, except perhaps for the purpose of a thorough examination, it is scarcely to be expected that persons really in the incipient stage of mental disorder will submit themselves to treatment as in-patients in an institution—be that a general or mental hospital. The Board agrees that it is probably during this incipient stage that the patient most clearly feels and realizes that something is amiss with himself, being then still in possession of sufficient insight, he can himself most effectively supplement and respond to the efforts of the physician. The importance, therefore, of providing, at this stage of the illness, treatment which is acceptable as well as effective is so manifest that the Board hopes for a large extension of this valuable service. It is encouraging to read of the out-patient centres now actively at work in various parts of the country, and we feel that the good which is thus being done by early and preventive treatment may eventually result in an appreciable diminution of the admissions to the mental hospitals.

*Mental Deficiency Act.*

As the Mental Deficiency Act has now been ten years in existence the Board has included in the report a general review of the work that has been accomplished under its provisions. The war, and the consequent financial restrictions coming so soon after the Act came into operation, greatly curtailed the possibility of its full development. The Board, however, considers that enough experience has been gained to make plain future possibilities and to point out the lines of further advance. Certain defects have been revealed in the Mental Deficiency Act; in particular it is not at present ensuring that unity and continuity of control which is necessary to secure adequate treatment for the mentally deficient, though the Act undoubtedly aimed at creating the machinery by which these conditions could be secured. The chief difficulty arises from the lack of co-operation between the authorities responsible for mental defectives. The Education Board is responsible for feeble-minded children from 7 to 16; the Home Office is responsible for those dealt with under the Children Act, and also through the Prison Service for adult mentally defective criminals; while the Ministry of Health, through the Poor Law, deals with very large numbers of all types and ages of the mentally defective. These central authorities have corresponding local authorities, and, although the Mental Deficiency Act created an elaborate system whereby a defective could be transferred from one authority to that of another, the Board of Control has found that, in practice, it is most difficult to secure complete co-operation between the various local authorities. They feel that it is still to a large extent true that "mentally defective persons pass from one authority or institution to another, helped or detained a little in each, but permanently for by none." In spite of the difficulties the Act has not been altogether unfruitful and under its provisions it has been possible to

## Reports of Societies.

### INSULIN IN GENERAL PRACTICE.

At the meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine held on October 9th, Sir WILLIAM HALE-WHITE presiding, a discussion took place on the use of insulin in general practice.

Professor HUGH MACLEAN, in opening, said that personally he had seen nearly a hundred diabetic patients who had been treated with insulin, and in every case the result was beneficial, often it was dramatic. He believed that insulin might be quite safely used by the average general practitioner, though stringent precautions must be taken and certain contingencies guarded against. The most important of these precautions was to go ahead very gradually. Short cuts must not be tried in general practice. Insulin when given carelessly might result in the death of the patient. The symptoms produced by an overdose of insulin varied considerably. Generally they consisted of flushing of the face, with sweating, often followed by some degree of pallor; often also there was a sense of constriction about the throat and chest, and giddiness and physical weakness might be present. The occurrence of these and other clinical phenomena was associated with the action of insulin in lowering the blood sugar concentration. When insulin symptoms were in evidence they were more severe the lower the blood sugar. But even though the symptoms of the hypoglycaemic complex might be very severe, fortunately they responded easily to treatment. The giving of sugar by the mouth would quickly remove the condition, so that there was little or no danger if the patient was carefully warned to take some sugar whenever any symptoms appeared. It was a good plan to keep a glucose solution (50 per cent. strength) ready to hand, and to instruct the patient to take from 1 to 2 oz. of this on the occurrence of symptoms. The effect of insulin on the diabetic condition was to restore the patient to the condition of the normal individual, though it was now generally accepted that insulin did not cure diabetes; while it was being administered the symptoms disappeared and the patient regained health and strength, but on stopping the insulin the symptoms returned. The general practitioner, to begin with, must make certain that he was not attempting to treat an unsuitable case. In general it was most important to be sure that the case was really one of diabetes or very marked glycosuria with high blood sugar content before giving insulin. In most cases the ravages of the diabetic condition were sufficiently obvious, but there were cases, often in elderly individuals, in which the examination of the urine showed a large amount of sugar, but no ketone bodies or only traces of them, and in which the patient was not emaciated, and might appear in quite good condition. In these cases a careful régime should first be ordered, and only if this was not successful in removing the glycosuria and materially reducing the blood sugar should insulin be employed. If a patient's urine did not give an acetone reaction great care must be exercised, and the possibility of "renal glycosuria," which it would be dangerous to treat with insulin, must be kept in mind. Occasionally one saw a patient in whom the diabetic condition appeared to be very severe, but whose response to diet was extraordinarily good; here insulin was not indicated. In a case suitable for insulin, the diet should first be arranged and the patient given the necessary amount of insulin to keep his blood sugar within normal limits. It was better to give a patient a moderately good diet with the maximum amount of insulin, even when such diet produced glycosuria, rather than to keep him on starvation diet, with which the glycosuria might be much diminished or even absent. The dieting and the dose of insulin should be carefully correlated. The patient should be placed on a fixed diet sufficient for his wants, and then increasing doses of insulin should be given until satisfactory results were obtained. The daily dietetic allowance should contain from 10 to 15 calories for every pound of the patient's weight. The protein allowance should be in the neighbourhood of half

a gram or less per pound weight, while the carbohydrate should be small, and the fat content comparatively high. Having arranged a definite diet, the patient should be kept in bed, or at all events indoors, for a few days at the beginning of treatment. His urine should be collected and examined each day for sugar and ketone bodies. The daily injections of insulin, beginning with 5 units in the morning and 5 in the evening, should be slowly increased until the urine became free from sugar, or until the dose given was one beyond which the medical man did not feel inclined to go. It was safer not to give more than 50 units a day as a maximum. The best time to give insulin was thirty minutes before the morning and the evening meals. If on reaching the extreme dose—which in a table he showed was 30 units twice daily—the glycosuria still persisted, it was well to continue for a little time with this dose, and to cut down gradually the carbohydrates of the diet. The majority of his own patients remained in good health and without glycosuria on a dose of from 10 to 25 units of insulin twice a day. The important point was not to hurry too much at the beginning of treatment, but to give progressively increasing doses over a fairly long period. In diabetic coma large doses should be given. The treatment might begin with an injection of 20-25 units, followed by a similar amount in two hours or less if no definite improvement took place. Sugar ought not to be given in these cases along with insulin; in certain cases it did no harm; but in some it seemed to neutralize the insulin. Generally in diabetic coma insulin acted in a dramatic manner, but its effect could not be forecasted with certainty.

Dr. GEORGE GRAHAM said that although insulin was of great value in diabetes it could not be regarded as a substitute for the ordinary dietetic treatment. Cases must still be dieted, though possibly not so strictly. The Toronto school, and also Allen and his co-workers, believed that insulin should be so used that the blood sugar curve became normal, and with this view the speaker was in agreement. Other workers both in America and this country seemed to think that the clinical appearance was of first importance; others held an intermediate view, that the urine should be sugar-free, but that it did not matter so much if the blood sugar was slightly raised. He gave an account of 23 severe cases treated at St. Bartholomew's, of which 19 returned to the normal blood sugar curve with insulin. From a study of the exceptions it seemed that there were some cases in which the normal blood sugar could never be reached. The insulin dose, which to begin with was one dose of 10 units a day, was gradually increased, but large doses should only be given while the patient was in hospital or nursing home under intelligent supervision. He had never sent patients out of an institution while they were taking more than 20 units in the morning and 20 at night. It was comparatively simple to bring down the blood sugar to normal if one waited long enough and gave big enough doses; the difficulty was to know what to do afterwards. At present he was aiming at gradually decreasing the dose of insulin as the patient improved until only one dose of 10 or 15 units a day was given; then he increased the protein and the fat of the diet, and delayed the addition of bread for as long as possible. While the result of the treatment of advanced cases of diabetes with insulin was quickly known, the result of the treatment of early cases could not be stated until some years had elapsed. To six patients who had had fairly recent attacks he was giving small doses of insulin, and was holding his hand with regard to carbohydrates; the result was yet to be seen.

Professor J. J. R. MACLEOD (Toronto) confessed to being somewhat at a loss in talking on the subject from the clinical side. The previous speaker had touched upon the possible value of small quantities of insulin. It was the experience of most of those who had used this method of treatment that, although it might not be possible with very small quantities to bring about any great change in the objective symptoms of the disease, it often resulted that the patient felt very much better in himself as a result of these administrations. He and his colleagues had lately been carrying out an experiment which bore upon this

## 28

The large hoppers of the hoppers and river service provide the key to the efficiency of the work. For each separate haul a separate hauler is provided and a separate hauler is provided for the purpose.

The sanitary control of the railway and river communications is carried out as follows: In each large railway station there is a real effective sanitary control, a medical officer is present at the arrival of each train from the south (the area of epidemics), and a medical inspection of passengers is carried out. This is not an individual examination but an individual questioning. Previous to the arrival of the

Mr. Green, and by Mr. Malcolm Scott and other artists from the College.

at the opening of the thirty-second session of the General Assembly of the Pharmaceutical Society of Great Britain, on October 3rd, the inaugural address was delivered by Dr. W. E. Dixon, F.R.S., Reader in Pharmacology in the University of Cambridge, who spoke on "Drug treatment: past, present, and future." Dr. Dixon said that he desired to give the students some reasons for believing that treatment by drugs was a part in its infancy, and to offer them, therefore, encouragement in their profession, which he believed had a great future and unlimited possibilities. The whole outlook on treatment had been altered by reason of the gradually accumulated knowledge that the animal body elaborated its own drugs, stored them generally at the seat of formation, and dolot them out to the tissues or used for formation, and dolot them out to the tissues or functions of the body were regulated, at least partly, by these natural drugs—of which adrenaline and pituitrin were examples—and it might be that all functions were of this nature, and that the object of a nerve supply was to localize the liberation of the drug in some definite situation. Obviously, then, animal products had assumed once again a great importance in pharmacy and pharmaceutical chemistry—such an importance, indeed, that some knowledge of the animal anatomy and physiology was almost an essential to the educated pharmacist of to-day, and he had little doubt that before long it would form a not unimportant part of the pharmacist's curriculum.

in the cure of disease due to the introduction into the body of some extraneous factor, Dr. Dixon pointed out that in several instances, especially in diseases due to protozoa, it was possible to destroy the causal agent of the disease by drugs; the action was not necessarily brought about by the direct effect of the drug on the causal agent. The organic compounds of arsenic had no decided effect on the spirochaetes or syphilis in the test tube, but they killed them in the body; sometimes, an alkaloid from a poisonous animal, such as the amoeba of tropical countries, except in the human body. Chemists and pharmacologists had as yet made little progress in their attack on bacterial diseases such as anthrax, but the fact that one of the appropriate doses, destroyed the micro-organisms in an experimental animal suggested a happy and successful way to treat the disease.

After stating some physico-chemical problems as to drug action which still awaited solution, the lecturer said that drugs might not be any particular action on the living matter, but because they collected in such quantities in the living cells as to clog the working of the machine. The chemist, had one common factor, the power of diffusion into living cells, comparative insolubility in water, and a greater solubility in fat and fat-like compounds. It was not a general rule, however, that drugs which exerted a selective action on some tissue tended to collect in that tissue; arsenyphine did not collect in the spinal cord, nor morphine in the brain. Absorption, or the concentration of soluble substances on surfaces, accounted for the action of some drugs. *Osmosis*, again, was the principal factor concerned in the action of the saline purgatives and diuretics. Dr. Dixon concluded with some advice to those students who were to become retail chemists: he spoke of their need for an understanding of life and of man, as well as for an accurate knowledge of the art of dispensing. The Dean (Professor H. G. Greenish) reported that negotiations with the University of London were making good progress, and he hoped that before the next session of the school they would have reached a satisfactory conclusion.

of diabetes, to which the name "renal glycosuria" had been given, did not present the usual clinical symptoms of diabetes, and the blood sugar curve at once differentiated cases of this class from those of true diabetes. The occurrence of glycosuria here was due to a low kidney threshold. In such cases insulin treatment would be very dangerous. All that was necessary was the restriction of carbohydrates within moderate limits and the avoidance of sugar in the dietary. Cases of glycosuria also were not infrequently met with in which the cause might be dietetic indiscretions, nervous shock, or some constitutional disturbance such as an acute toxæmia from a septic focus. In such cases rest and appropriate dietetic and other treatment might lead to rapid disappearance of the glycosuria. The plan of treatment to be adopted depended upon the persistence of the glycosuria and the character of the blood sugar curve. Clinical observation was of first importance. In certain cases, as in elderly or tuberculous people, a too strict adherence to a rigid dietetic treatment might do more harm than good. Each case must be treated on its merits. When a diabetic condition was established it was essential, unless there were special contraindications, that a definite course of treatment be carried out. One of the most important considerations in the treatment of diabetes was the possibility of infection. It was well known that severe glycosuria might result from the toxæmia of acute infections, and clear up when the septic focus was removed. His experience at St. Mary's had been that the removal of any focal sepsis in diabetic cases improved the tolerance in every case, and in some cases of diabetes of several months' standing raised the tolerance practically to normal. If a toxic focus was present in diabetes, insulin was not going to do any good, for the effect of the septic focus was to neutralize the insulin. This fact, he thought, explained insulin failures. A septic focus must be sought for very carefully. The ordinary examination of the teeth was not sufficient; they should be examined radiologically. Similarly the most careful examination should be made of the tonsils. The removal of the septic focus was not attended by danger, provided proper precautions were taken. In the severe cases of diabetes, with a low tolerance and hyperglycæmia, insulin was invaluable. It was also of great value in cases where acid intoxication was present. But the haphazard administration of insulin in diabetic cases was not likely to lead to any permanent benefit, and, moreover, was fraught with danger. Only along methodical lines were good results to be expected. If an ordinary dose of insulin was given to a person with a normal blood-sugar curve it had no toxic effect, owing to the neutralizing action of the blood sugar, and therefore some might assume that it would be feasible to give three or four times the normal dose. This, however, was not the case at all, for the simple reason that these diabetic patients had no sugar reserve. Another precaution which he mentioned was the undesirability of giving insulin after midday. A 10-unit early morning dose might be given, perhaps increased to 15 or 20 units, and in a severe case a third of the early morning dose might be given at midday, but not later.

In conclusion, he said that there was no question that insulin in severe cases had markedly beneficial effects. It was of the utmost value where acidosis was present and coma was threatened. In cases where acidosis was present it was well to give fairly large doses of insulin, and with the insulin to give glucose by the mouth, and a fairly liberal allowance of sugar. Up to the time of the discovery of insulin diabetic coma was incurable, but now there were quite a number of cases reported of complete recovery after diabetic coma had developed. The cases which failed were cases in which the coma arose when something more than the pure diabetic condition was present.

### NEWCASTLE AND NORTHERN COUNTIES MEDICAL SOCIETY.

The first meeting of the new session of the Newcastle-upon-Tyne and Northern Counties Medical Society was held in the Royal Victoria Infirmary on October 4th. The President, Dr. R. Esmond Moyes, was in the chair, and about

one hundred members were present. A large number of medical and surgical cases were demonstrated by the following members: Professor W. E. Hume, Drs. George Hall, G. A. Berkeley-Cole, S. Whately Davidson, J. C. Spence, Professor H. Brunton Angus, Messrs. Hamilton Drummond, W. A. Hewitson, H. Harvey Evers. A series of pathological specimens from the museum of the University of Durham College of Medicine was arranged by Mr. W. E. M. Wardill, the Curator.

The Society meets monthly during the winter session, and in addition to the ordinary meetings two clinical and pathological meetings have been arranged for the convenience of country members, at 4.30 p.m. on October 24th, and January 23rd, 1924. The annual address and dinner will take place on December 6th. On February 7th, 1924, an address will be delivered by Dr. Hugh Thursfield, London, and on March 6th a discussion will be opened by Dr. Leith Murray, Liverpool, on "Caesarean section, its history, indications, and limitations."

### CELTIC MAN ON THE SUSSEX DOWNS.

A SPECIAL meeting of the Brighton and Sussex Medical-Chirurgical Society was held on September 22nd, 1923, when the President, Dr. ELIOT CURWEN, F.S.A., departing from the usual custom, invited the Society to Park Brow, a hill in the parish of Sompting, and there delivered his presidential address on "Celtic man on the Sussex Downs." Beginning with a survey of the geological and climatic conditions of Sussex in prehistoric times, he proceeded to show that the chalk areas in the south-east of Britain supported the most settled and civilized inhabitants of the country during the five or six centuries which preceded the Roman conquest. He spoke of the great quantities of corn which were grown in the south-east parts of Britain from the time of Pytheas (323 B.C.) till the end of the Roman occupation, and then proceeded to demonstrate on the ground the evidence still remaining that Park Brow was inhabited from the beginning of the Early Iron Age (about 550 B.C.) to the fifth century A.D. He pointed out the "lynchets," or cultivation-balks, of the Celtic fields, and explained their characteristics and the manner in which they were formed; he also demonstrated what he stated to be one of the longest and most interesting stretches of Celtic road in Sussex. The members then walked down this road to the circus, or moot, of the Celtic community, and when they were seated on its low, broad banks, the president explained its origin and character and the purposes to which it was put. Attention was next drawn to the site of the town, or village, at the entrance of which the circus was situated, and the character of the dwellings was described. A storage pit for grain, 6 ft. deep and 8 ft. in diameter, was then shown, and it was pointed out that the pottery found therein belonged to the Hallstatt and earliest La Tène periods, about 500 to 400 B.C. Evidence was adduced to prove that the early inhabitants on Park Brow spun their own wool or linen, and wove it into fabric; and after a brief description of the ground culture attained, as shown by Early Iron Age finds elsewhere, an endeavour was made to obtain an insight into the mind of the late Celtic inhabitants of the land by the evidence offered (if they might be taken as genuine) by the Triads of Moelmad.

At the annual meeting of the Association of Certificated Blind Masseurs Sir Robert Jones, the president, referred to the progress made by the association during the past year. At the end of this, the fourth, year of its activities, its members numbered 160, 81 of whom were blinded soldier masseurs, 37 civilian masseurs, and 42 masseuses. The thanks of the association were due to St. Dunstan's Hostel for £448, and the National Institute for the Blind, which had made a grant of £224, to further the work of the association. The income for the year was £248, and there was a balance in hand of £64. Sir Robert Jones pointed out that the association was not of the nature of a transient war charity, as 79 of the 160 members were civilians. He insisted that the notion that a blind masseur could not equal the skill of a masseur with sight had no foundation in fact; the blind were, indeed, specially suited to become masseurs, and they acquired in certain directions a deftness and delicacy of touch not often met with in an ordinary masseur.

which very many have broken down." Thus a recent writer in a Communist paper stated that 75 per cent. of the Communist party were ill as a result of strain, overwork, and war conditions, and the general level of health of all towns-people has certainly deteriorated. It is only this year, for the first time, that Communist leaders, Government officials, and important workers in all grades have been able to take a holiday. The trains to the health resorts of the Caucasus and the Crimea (a Russian Riviera and very beautiful) have been packed, and tickets were only obtainable with difficulty. But the taking of holidays is probably at least a sign of the strain relaxed and this will probably be reflected in a general health improvement at a later date.

Scotland.

This Society met in the rooms of the Glasgow Medical Club on October 4th, when Dr. J. Grant Andrew delivered his honorary presidential address on "Mebere and the state of medical practice during the grand sick." The battle of the Glasgow Medical Society.

ment of the three great corporations in Paris in the seventeenth century were recognized and the narrow boundaries of the humoral view of medicine were traversed. Dr. Andrew noted that three of the great discoveries of the century—the circulation of the blood, and the therapeutic use of quinine and antimony—were counted by the faculty for the pastures of reason. The profession of those days made an admirable but for the shafts of a great satirist, himself a sufferer at the hands of pelicans and charlatans, and the change from the light rattle of the earlier plays, to the ferocity of the later attacks was well brought out by the speaker. Before the address, the President (Dr. D. George Carmichael) presented Dr. Grant Andrew with the diploma of the society, and referred appreciatively to his public work in Glasgow before leaving that city to make his home in Bournemouth.

Post-Graduate Study in Glasgow.

Glasgow has induced the board of the Glasgow Post-Graduate Medical Association to make arrangements for graduate teaching in Glasgow on similar lines during the coming winter, from November to May. The teaching will be available in three forms: (a) weekly demonstrations, (b) special courses, and (c) clinical assistants. A series of demonstrations will be given on Wednesday afternoon, and has been arranged with the following subjects:

[illegible]

various subjects. The special courses include one to be carried on at the Royal Infirmary, the Royal Hospital for Sick Children, and the Royal Maternity and Women's Hospital, providing opportunities for the study of a number of closely associated subjects connected with the welfare of the mother and the newborn infant. A course on gynaecological surgery will be conducted in the Western Infirmary. A course of eight meetings upon medical ophthalmology will be conducted by members of the staff of the Eye Infirmary, the Ophthalmic Dispensary, and the general infirmaries; these meetings will be general in character.

Quintus.

BELFAST MUNICIPAL SANITARIUM.

TYPHUS FEVER IN MAYO.

At a recent meeting of the co. Mayo Board the Minister of Local Government forwarded the occurrence of cases of typhus in Belmullet district, the report of Dr. O'Dwyer Inspector, which was as follows:

I have been in Belmont for some time endeavoring to make the most of it. I have been in Belmont for some time endeavoring to make the most of it. I have been in Belmont for some time endeavoring to make the most of it.

[illegible]

*Amphimachus*.—Three more ambulances in connexion with the hospital are required to repair or broken up, and the local contractors undertake to repair them. I consequently had to send Dr. Williams and also utilised it to bring to Berlin. A would make the following suggestion to the Ministry:

*Squad*—It is absolutely necessary to have a staff always. When an outbreak takes place it too late by the time arrangements have been made. The members of the Board of Health that they would suggest a nurse constantly in the hospital.

are devoted to a very full and detailed description of migraine, only two pages are allotted to myasthenia gravis. The account of the symptomatology of cerebral tumours is disappointing and there is no mention at all of tumours of the third ventricle.

Vascular lesions of the brain are dismissed much too shortly, and we consider that the authors go too far in their avoidance of any clear differentiation between haemorrhage, embolism, and thrombosis. The student in search of an account of the sensory disturbances in cerebral lesions must look for them in the chapter on cerebral apoplexies; this surely is a defect in arrangement.

The various forms of syphilis of the nervous system are described together in one chapter, for which we have nothing but praise. Here the important question of treatment is fully discussed. The general symptomatology of the lesions of the brain stem and cerebellum are well described, with the aid of numerous diagrams, many from Dejerine's classical textbook. Anatomical and physiological considerations throughout receive careful attention and this is a valuable feature of the book.

Undoubtedly the most debatable aspect of the whole book is its treatment of the neuroses in general and of their etiology in particular. The authors are whole-hearted followers of Freud and present their case accordingly. Had other views been allowed more consideration this section would have had greater value.

The section entitled the endocrinopathies contains many hypotheses which are presented as though they were facts, a criticism which applies also but with less force to the section on vegetative neurology. The chapters on mental diseases are short and concise; they succeed in conveying a satisfactory account of the symptoms and nature of the more common psychoses.

The illustrations are very numerous, and in most cases good, though suffering in some instances from too much complexity.

The fastidious English reader will probably find many expressions to which he may object, and some sentences the exact meaning of which he may legitimately be excused from appreciating. In a short review it is difficult to draw attention to all the points which invite criticism; while cordially welcoming this edition we have thought it right to emphasize some aspects of the book in which we think it falls short of being an ideal textbook for students. Of great value to the senior and experienced student, it is perhaps too unwieldy for the capabilities of the junior, as well as too one-sided in some of its views; yet, without doubt, it is a monument of industry and, read with discrimination, a very valuable addition to the library.

### URGENT SURGERY.

THE English translation of Professor LEJARS's well known book, published with the title *Urgent Surgery*, was carried out so well by Mr. W. S. Dickie and Mr. Ernest Ward, that it has now reached its third edition.<sup>3</sup> It has been prepared to accord with the eighth French edition. All the chapters have been revised, and have undergone some modifications, embodying the lessons of war surgery. Thus the work of Fiolle and Delmas is used in the description of ligation of the vessels, and most of the surgery of accidents bears the imprint of our more recent acquisitions of knowledge. Professor Lejars is, however, an excellent and discriminating author, who knows well what to choose and what to leave out. He gives as a rule no more than one method of treatment, and does not obfuscate the issue with a mass of alternatives and irrelevancies. We doubt the wisdom of the advice given on page 782, to curette the medulla in acute osteomyelitis. A sufficient removal of bone cortex allowing of free medullary drainage is equally efficacious, is more in accord with general surgical principles, and less likely to lead to death of the bone

with subsequent sequestrum formation. The section on whitlows might well be revised in future editions. The book, we have no doubt, will continue to make a wide appeal. It is ideal for the occasional operator, for the practitioner who may be called upon suddenly in some emergency to relieve, say, an acute abdominal condition. Such are happy to have so wise a mentor and one who so clearly expresses his meaning. In this respect no little credit is due to Mr. Dickie and Mr. Ward, who have made a model translation, neither distorting the author's meaning nor substituting their own personalities for his. The production of the book is well worthy of Messrs. Wright and Sons' high reputation, and the thousand illustrations are in every way admirable.

### PHARMACOLOGY AND THERAPEUTICS.

THE *Text-book of Therapeutics*, including the essentials of pharmacology and materia medica, by Dr. A. A. STEVENS, is a well established and standard textbook, for it was first published in 1895. The fifth edition appeared in 1916, and the new (sixth) edition<sup>4</sup> has been practically rewritten and descriptions of twenty-five new drugs introduced. The author states that the object of his book is "to present a concise description of the most important pharmacological reactions and to show their practical use in influencing the various disturbances that occur in disease." It is a large book (793 pages), and as the title indicates it covers a wide range, for it is practically an attempt to combine a textbook of pharmacology with an index of therapeutics.

The author deals first with the pharmacology of drugs, classifying them roughly according to their chief actions; and in the last third of the book the treatment of different diseases is discussed. The unfortunate gap that exists between the teaching of pharmacology and the practice of therapeutics is notorious, and the attempt Dr. Stevens makes to bridge this gap by including the two aspects of the subject in one volume is laudable, but the arrangement naturally leads to a certain amount of duplication.

The account given of the pharmacological action of drugs is clear and concise, and in most cases embodies the latest information on the subject, although the description is to a certain extent hampered by the absence of illustrations. A few of the statements, however, seem scarcely to represent the latest knowledge. For instance, the production of spinal anaesthesia by cocaine is described, and it is stated that the death rate in spinal analgesia by cocaine probably exceeds 1 in 1,000. Later on it is mentioned that cocaine as a spinal anaesthetic has been superseded largely by less toxic substances, such as tropacocaine and stovaine. This scarcely gives a correct impression of the methods usually practised, for those surgeons with most experience of the method agree that cocaine should never be used as a spinal anaesthetic, and claim that the mortality of spinal anaesthesia is far below 1 per 1,000 when a proper technique is employed.

The general classification of drugs is always a difficult problem, and that adopted by the author might in some cases be improved; for example, the general term "alteratives" is made to include arsenic, iodides, colchicum, and extracts of endocrine glands. The pharmacological section is followed by a section of forty pages describing the action of heat, light, electricity, x rays, massage, bleedings, and transfusion. Descriptions are given of the treatment of a selected list of diseases, and in each instance treatment as a whole is described, and not merely drug treatment. But the space at the author's disposal (200 pages) has been too limited to allow him to give a complete account; for instance, rickets is dealt with in one page.

The chief criticism we have to make is that the author has tried to get too much into one volume. In the pharmacological section an account is given of all the drugs in common use, with the result that the actions of the more important ones are described in rather a summary fashion;

<sup>3</sup> *Urgent Surgery*. By Félix Lejars. Third English edition. Translated from the eighth French edition by William S. Dickie, F.R.C.S., and Ernest Ward, M.A., M.D., F.R.C.S. Bristol: John Wright and Sons, Ltd.: London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd. 1923. (Sup. roy. 8vo, pp. xiv + 803; 20 plates, 1065 figures. 65s. net.)

<sup>4</sup> *A Text-book of Therapeutics, including the Essentials of Pharmacology and Materia Medica*. By A. A. Stevens, A.M., M.D. Sixth edition. Philadelphia and London: W. B. Saunders Co. 1923. (Med. 8vo, pp. 793. 30s. net.)

than to be burdened with a colotomy for life and with a rectum occasionally discharging urine as well. The operation he advocates certainly cures the incontinence of urine, but is not recommending a greater evil than that which he set out to cure.—I am, etc.,  
MERCER, SEPT. 25th.  
LESLIE DUGGER, M.B., M.R.C.S.

#### ETHER VERSUS CHLOROFORM

Sir,—The recent correspondence has, somewhat surprisingly, taken no account of the mixture of these two anaesthetics which has been extensively employed in recent years; it has undoubtedly conveniently, and has been extolled as an eminently "safe" anaesthetic agent. As a matter of fact the "safety" of chloroform and ether mixtures has been grossly overestimated, as is shown by the statistics recorded in recent reports of the Registrar-General, which are as follows:

In 1921 the return of deaths under pure chloroform was 75, under chloroform and ether 23, and under A.C.E. mixture 7. In 1920 the deaths under pure chloroform were 53, under chloroform and ether 22, and under A.C.E. mixture 12. The original intention of mixing chloroform with a less toxic agent was to dilute the chloroform vapour, and so minimize its lethal properties. From the point of view that chloroform kills solely by over dosage, no doubt the reasoning was good, but unfortunately the premises were wrong, and the cold logic of the figures quoted above will do much to remove the still prevalent idea that the inhalation of an attenuated vapour is the royal road to safety.

In using chloroform it is essential to follow precisely the degree of its own particular anaesthetic effect; this is obscured by admixture with other anaesthetic vapours, and to a death under C.E. mixture may be a particularly insidious event, and difficult to guard against: it is, I believe, far easier to take suitable precautions when using pure chloroform. I feel sure that the lethal potentialities of chloroform mixtures are unknown to the majority of those who employ them, and I trust that the few words of warning may be of service.—I am, etc.,  
LONDON, W., SEPT. 25th.  
A. G. LEVY.

#### REPEATED TAPPING IN ASCITES.

Sir,—I have under my care a man, aged 38, who, after being out of sorts for some time, one morning last February got up out of bed vomited a bowlful of dark blood mixed with food. About eighteen years previously he had syphilis and had been treated for it. I found that he had parasites of the left external rectum, causing diplopia. I referred him to an eye specialist, who, finding the Wassermann reaction positive, gave him six injections, at intervals of a week—except on the last occasion, when the interval was two weeks—of novarsensodium, beginning with 0.5 gram and increasing to twice that dose. The diplopia improved, but when I saw the patient again he had ascites, oedema of the legs, some vomiting, slight jaundice, and conjunctival injection. The abdomen was tapped and over 240 oz. of straw-coloured and somewhat milky fluid was drawn off. At a consultation the opinion was expressed that he was suffering from arsenical poisoning and cirrhosis of the liver. Afterwards he was tapped at intervals of four to six days, and there were no nodules. The urine was very free from albumin and measured about 24 oz. in twenty-four hours. In July he again vomited dark blood; about the middle of September continuous drainage was instituted by means of a Jacques rubber catheter kept in as suggested by Sir John 1920. The treatment had to be discontinued as the catheter became blocked with yellowish debris and there was considerable pain and depression. The patient is now again being tapped every four or six days, but the amount withdrawn is decreasing, owing to formation of adhesions, probably due to ingress of air when the catheter slipped out. The question is whether it is desirable to continue the tapping. Cases have been recorded in which a tolerable

state of health has eventually resulted, accompanied by great variability of the abdominal surface, but in this case the question arises whether there may not be a splanchnopleurion, possibly a granuloma, to account for the portal obstruction, which obviously exists.—I am, etc.,  
A. E.

#### PAY OF THE R.A.M.C.

Sir,—The letter of "Major R.A.M.C." in your issue of September 25th (p. 587) gives a perfectly accurate account of the chief grievances of the officers of the R.A.M.C., which may be summed up as inadequate pay, frequent and expensive moves, specialist pay given with one hand and taken away with the other, slow promotion, no rise of pay after fifteen years' service, and too much foreign service. As the result of these unsatisfactory conditions the corps is melting away rapidly. Almost every *Gazette* contains the names of majors and captains R.A.M.C. returning voluntarily. Officers tell us that a little new blood will do the corps no harm. But unfortunately the corps is bleeding to death and no new blood is available. How can it be saved? It would be nothing short of a disaster if the R.A.M.C. were to follow the I.M.S. into the pit of oblivion. I do not profess to be able to find a solution for all the points of the problem. It would be easier to get blood from a stone than to return an increase of pay or pension from the Treasury, but every effort should be made to place would certainly give the corps its quietus. The frequency of moves is due to some extent to the shortage of officers, and to such extraordinary calls as was made by Constantinople, but every effort should be made to reduce them. The juggling over specialist pay is a very sore point, and one which could easily be rectified. The Treasury rule is that when an officer holds a permanent or semi-permanent appointment he must pay income tax on his lodging and furniture allowances. The result is that a specialist's appointment, which is nominally for three years, though it carries with it the extra pay of 2s. 6d. or 5s. a day, renders its holder liable for income tax on his allowances. Now these appointments are not the fact-permanent appointments. They are liable to be interrupted by many different amenities. I could quote several instances where officers holding so-called permanent appointments, each supposed to last three years. Therefore, as they are not by any means permanent appointments, why call them so? Let it be an understood thing that a specialist will not be moved more often than is absolutely necessary, and leave it at that. His 2s. 6d. will then be worth at least 2s. to him instead of 5d., as it is at present.

The fact that there is no provision made for any rise of pay after fifteen years' service except on promotion is evidence of a serious oversight on the part of those responsible for the Royal Warrant. Such an injustice should have been committed intentionally, and the mistake should be rectified by giving a rise of payment at twenty years. I now come to the burning question of the large proportion of foreign to home service, which may be as much as two-thirds foreign to one-third at home, and is never less than one-half. This is the matter above all others which makes for the unpopularity of the corps. The first tour of service in India may be not only tolerated but enjoyed, but to the married man the second and third tours are the events he dreads most in his service. Separation, expense, ill health, bare all to be faced without any compensating advantages, now that life in India is no longer cheap, and Indian pay is little if any more than home pay. The only remedy for this unhappy state of affairs seems to be the creation of an Indian branch of the R.A.M.C. on similar lines to that of the Royal Engineers. Let the officers of the R.A.M.C., like their R.E. brothers, be allowed after a few years' service in India to volunteer for a further tour of service in India, and Indian pay is little if any more than home pay.

581

at the time of his report, one had recurrence; nine of the cases had died; the history of one could not be traced; and the survivors had lived from one to twenty years after the operation.

### HUMAN EMBRYOLOGY.

THE manual of human embryology<sup>7</sup> written by M. VIGNOLI is a primer or synopsis composed at their request for first and second year students. The author states that at first he refused the request, but finally decided that a book of the kind was needed, since the student of to-day has too little time at his disposal to permit of his devoting more than a week to the study of embryology and requires only summary notions of the subject, enabling him to pass his examinations and comprehend the development of the principal organs. The aim of the book is therefore modest and does not embrace more than the A, B, C of the subject, which is presented in a purely diagrammatic form. Such being the author's aim, it may be said that he has carried it out with great skill. The arrangement of the subject matter is good and the descriptions, although short, are clear and sufficient. The author has made a point of rendering his statements comprehensible to the student; every page, before going to press, was submitted to a student and passages considered to be obscure were rewritten.

The book contains one hundred and ninety-six diagrams there is scarcely a statement that is not illustrated in figures. It is divided into three parts. The first includes the study of fecundation, segmentation, development of the embryonic area, and the differentiation of the embryo and adnexa. The second part includes the development of the ovum in the uterine mucosa. The third deals with the development of the embryo and its principal organs; and the fourth with the full-term foetus and membranes. An explanatory list of embryological terms in common use is given in an appendix.

### NOTES ON BOOKS.

A THIRD edition of the *Manual of Instruction for the Royal Naval Sick Berth Staff*<sup>8</sup> has been issued by H.M. Stationery Office. It has been prepared by Surgeon Commander G. O. M. DICKENSON, R.N., who has thoroughly revised the volume and rectified several errors of omission and commission. The alterations thus effected, according to the author, are of an extensive character. The thirty-three chapters cover a very wide range of medical subjects—from somewhat more than elementary instruction in anatomy and physiology to descriptions and treatment of surgical conditions and diseases, both general and systemic. General nursing, cookery, anaesthetics, pharmacy and dispensing, and a variety of regulations, preparations for a naval action, landing parties, care of the feet and of surgical instruments, and sick subjects which probationary sick berth attendants and sick berth staff are expected to know complete the volume.

One can only say that if they assimilate all that is contained within the covers of this manual they will have a very wide elementary knowledge of the science and practice of medicine and surgery. In some respects the information contained in it is not quite up to date. It would be as well, for example, to emphasize in a future edition the use of the Thomas splint for fractures of the extremities. Its use for this purpose is only cursorily noted, whereas, as the result of experience in the late war, it is in the R.A.M.C. training one of the most important features in the instruction of the orderlies. Again, although there is much detailed instruction regarding bacterial infections, toxins, and antitoxins, there is no mention of the prophylactic use of inoculations in the description of enteric fever. Amongst the many diseases sickness, there is no mention of sandfly fever, which is so common on the Mediterranean littoral, and would therefore be, it might be supposed, of some importance to the naval sick berth staff. The risk of overcooking of vegetables and meat—an extremely practical point in the prevention of scurvy—has not been noted. It is suggested that the author in a future edition might consider these points. The print is clear and the illustrations numerous and good.

<sup>8</sup> Manual of Instruction for the Royal Naval Sick Berth Staff. By Surgeon Commander George O. M. Dickenson, M.B., B.S. Durb., R.N. London: H.M. Stationery Office. 1923. (Cr. 8vo, pp. 523; 262 figures.)

### MEDICAL DEFENCE UNION.

THE annual general meeting of the Medical Defence Union was held at the Royal Hotel, College Green, Bristol, on Saturday, September 29th, 1923. The President, Sir Charles Ballance, K.C.M.G., C.B., M.V.O., occupied the chair, and upwards of thirty members were present.

In moving the adoption of the annual report of the Council for the year 1922-23, the President said that he was glad to be able to congratulate the members upon the continued expansion and satisfactory progress of the Union. On only one previous occasion had the annual meeting been held in Bristol, and that was fourteen years ago. At that time the membership was approximately 7,700; now it was over 10,700. The income of the Union then was only a little over £4,000; now it was over £10,000, and with this improvement in the financial position the Union was able to do far more for its members than formerly. Every additional member meant greater protection for all, and medical practitioners should realize that in joining the Union they were not only protecting their own interests, but were doing something for others. One noticeable feature of the last few years had been the increase in the number of women members. Over 400 women doctors had now joined the Union. Three women were on the Council and their advice had been most helpful in many cases. Efforts had recently been made to induce the Union to make some concession to those practitioners who were also members of the British Medical Association, but the Council had declined to make any differential treatment in favour of B.M.A. members. Similar overtures had been made to the London and Counties Medical Protection Society, with the like result. Both the protection societies felt that they were mutually concerned in maintaining complete independence, and with a view to the promotion of good feeling, and, where necessary, co-operation, a Standing Joint Committee, consisting of representatives of each society, had been constituted and would meet at regular intervals.

The transfer to the new offices in Bedford Square had been effected without any serious interruption to the work of the Union, and the change was much appreciated. In view of the higher costs of litigation, the Council had thought it prudent to raise the amount of the insurance indemnity after January 1st next to £3,000, the improved financial position of the Union enabling the Council to provide the additional cover without any increase in the annual subscription to the Union.

The President specially pointed out that charges of negligence and malpractice against medical practitioners were no less frequent to-day than formerly. By far the greater number of the allegations which doctors were called upon to meet were a mere pretext for evading the payment of professional accounts. He could not conceive how anyone engaged in active practice could be so foolish as to refuse to avail himself of the protection which an organization such as the Medical Defence Union afforded. He regarded membership of a defence society as equally important with registration as a medical practitioner, and was glad to find that the newly qualified were joining the Union in increasing numbers.

The annual report of the Council and the statement of accounts were adopted. Dr. M. Hallwright, Dr. W. Rigden, and Dr. H. Robinson were re-elected members of the Council.

On the recommendation of the Council the following resolution was unanimously adopted:

"That the Council of the Medical Defence Union, having full discretion under the articles of association as to the cases which it shall undertake on behalf of a member, shall have full discretion in any case in connexion with divorce proceedings to withhold or partially withhold the indemnity insurance afforded to members in respect of damages and costs of the other side which may be awarded against them."

A hearty vote of thanks was accorded to the President and Council for their services during the past year. The Council, at its meeting on October 4th, unanimously appointed Mr. Walter G. Spencer, O.B.E., F.R.C.S., president of the Union for the ensuing year.

which is another way of intimating that the tests of silence and so forth were very searching. The principle of the construction is to embrace a considerable amount of aeronautical engineering practice. Nevertheless the lines of the coachwork can be made whatever the purchaser desires. The main features of the construction scheme consist of putting a flat platform on the chassis, and mounting the seats, instrument board, and so forth on that, the sides and roof of the covered body being a quite independent unit, and constituting a shell. It is a cheap body to make; and no coachwork so durable has been brought forward before. The one point of objection may be that, when it is brand new, it has not that mirror-like surface that can be got by ordinary systems of construction. Against this is the fact that these surfaces deteriorate sadly in anything from a month to three months' service; whereas the Weymann finish remains in its pristine condition for two or three years and, even thereafter, it is practically none the worse for wear. Things can be done with this construction sideways, any other. Thus a door may be forcibly twisted shape, none the but on release flies back into its normal shape, none the worse. A very ingenious cam action is the principle of the wholly original door-lock, ensuring silence and absolute security. The lightness of the construction enables a chassis to behave with full scale, luxuriously equipped, and large covered body as though it had a two-seat open racing shell on it. For instance, on a large Renault the whole body, including the very ample cushioning and so forth, scaled 5½ cwt. only, with all the usual glass and so forth.

#### What Doctors Need.

All the joints in this type of body are separated, as to their component parts, by canvas. The panelling is of a special synthetic leather which has some quite extraordinary qualities. For instance, in hot summer weather the car may be driven all day in scorching sun with an opening in the front windscreen only, so that the driver is protected from heat and dust, yet on getting out, though he will find the panels bulged somewhat here and there, yet by the time he has had lunch the coachwork will have reassumed its normal shape. In like fashion one of these panels may be punched really hard, and a welt raised on it. But, again, after a short time search for the blister will be in vain. Rather a curious story attaches to this quality. The inventors thought that, if this material were so serviceable for coachwork, what a fortune could be made in boots! After wearing boots fashioned of this synthetic leather for a fortnight, however, and finding that they came back to their original shape every morning, so that the user had the discomfort of putting on brand-new boots every day, it was realized that this quality was rather a disadvantage than a gain. All the sliding windows of the Weymann bodies are fitted in rubber channels. This body is, in effect, resilient and free from strain. The methods of construction and the materials used enable wringing stresses to be withstood; and the rattle-free condition of the machine is permanent. This type of coachwork has other important qualities from the point of view of the medical man in that, whereas one dare not dust an ordinary body because the surface would become scratched and lose its gloss, and one has to be very particular about washing for the same reason, by contrast this type of panel can be washed or dusted, in quite an unskilled fashion, without the vehicle losing its original appearance. The cheapness enables a limousine, or saloon body, as well as the landaulette type, to be produced at a cost not exceeding 10 per cent. more than that of constructing an open touring type body, the weight being approximately three-fifths only of the weight of a body of a similar style constructed on ordinary coachbuilding principles. Altogether it constitutes a very notable development of prime interest to the medical man at this juncture. There is nothing experimental about it, the type having been tested over several years. Further, never has such a degree of engineering knowledge been brought to bear on the problem of coachwork construction as is embodied in the very clever framework employed by

the Weymann principle. And the saving of voice strain in the course of a day's run has to be experienced fully to be appreciated.

#### Large Section, Low Pressure Tyres.

In 1916 the Dunlop Company experimented with large section, low pressure tyres. At the Paris Show a number of vehicles, particularly of the smaller sorts not over well sprung, are exhibited with proportionately very large section Michelin tyres, which will constitute a feature of exhibits at the forthcoming show at Olympia, where a number of vehicles will also be shown with Dunlop tyres evolved independently on this principle. From the purely technical point of view it should be pointed out that this is quite a different thing from fitting over-size tyres because these new style "comfort" or "balloon" low pressure, large section tyres are set on very wide rims, so that the strain on the walls is reduced materially. The main object is to ensure comfort on an ill-surfaced road. In other words, the tyre industry is here bringing forward something to cover the faults of the automobile engineer who does not understand springing, or who has not the money at his disposal with which to supply adequate springs to his vehicles. At an earlier period I should have regarded the development as dangerous. But now that the corded tyre principle can be exploited without infringing patents and is, therefore, being taken up universally as being by far the best method of cover constructing, these tyres can be run under conditions of relative abuse with much greater safety, and under-inflated to give very much better results along these lines than have been attained hitherto. Michelin offers 715 by 115 mm., 750 by 130 mm., and 775 by 145 mm. "balloon" or "comfort" tyres to replace the 80 mm., 90 mm., and 105 mm. sections.

One inevitable result of this new movement, however, will be that people will run anything from pedal bicycles to motor cars with ordinary tyres at low pressures. That nothing could be more extravagant, or dangerous. Such pneumatics are not designed for running below the pressures specified and there is grave risk of them coming off the rims at corners, and so forth. The over-size "comfort" tyre, as the new type is styled which is being produced by the industry both in the Old and in the New World, is designed for the special conditions it has to fulfil. Michelin even introduces a special type of safety ring which prevents a deflated tyre coming off at high road speeds, as has been demonstrated on the Continent on some racing cars. The roads there are less satisfactory on the whole than in this country and, of course, cars are driven at vastly greater speeds, for one thing because the open, level, and straight roads encourage that; for another because the surfaces are not treated for dust, therefore you must scorch or be choked with dust of other folk's raising. A number of automobile engineers who have tried these tyres on their cars state that the increase of comfort is great. But they find that when corners are taken at high speed, they seem to experience an inclination to sea-sickness.

There are many other interesting inventions in the Paris Show, but the majority are of no more than academic interest to medical men; incidentally, this applies to Mr. George Constantinesco's new form of transmission to dispense with clutch, gearbox, and back axle drive on a motor car. Whatever its merits this could not be standardized by manufacturers in this country for the coming season. The device has been evolved by the inventor of the "C.C." gear whereby machine guns were fired in war time through propellers of aeroplanes.

The Cambridge University Press has recently published for the Cambridge Philosophical Society the first number of a biological part of the *Proceedings* of the society, which until now have contained, in a single series, mathematical, physical, chemical, and biological papers. In separating the medium will be papers from the others it is hoped that a medium of general interest done in the various departments of the university and possibly elsewhere. A Publication Committee, consisting of professors and other representative biologists, has been appointed. It is proposed to issue the new *Proceedings* in quarterly numbers.

and are thus the distributors of large sums in cash benefits weekly; formally they have an extensive control over the National Health Insurance Fund through which vast sums of money, contributed by insured persons and their employers, and added to by the payers, pass every year, and out of which credits are assigned to the various societies according to their membership. Some of these societies are very large; some are very small. Some are highly centralized; others have thousands of branches throughout the country, and for purposes of valuation and many other purposes these branches are autonomous units. All of them have secretaries, large or small. Many other offices in societies and groups of societies have been created. Some are filled wisely; some not; this is natural enough. Altogether there has grown up in this way a great vested interest, with great power for good or otherwise, in organized communication with millions of people, controlling or having powers of obstruction with regard to large sums of money, and wielding therefore a great political influence.

From the beginning the medical profession has seen that one of the dangers of the insurance scheme was that approved societies might become so dominant as to usurp the place of the community, and by dictating to Ministers control the whole service, including medical benefit, from the administration of which they were, as such, excluded by the efforts of the medical profession in 1912. Recent events have shown that this danger has become a real one. The profession has shown its willingness to provide the services which the State asks for, and to arrange with the representatives of the whole community—Parliament, the Minister of Health, and the Government—the terms on which it will provide them, but it may be taken as certain that it will unite in refusing to become subservient to any particular section, however powerful. The representatives of approved societies are now engaged in directing the Minister of Health what fee he must pay insurance practitioners for their services, and forbidding him to advance one penny on what they are willing he should give. The view they take is narrow, but the Minister seems himself to have adopted it: it is that the sum must be the lowest for which any barely sufficient number of doctors can be obtained to attend their members when ill. We are sure that many of the officials of the societies appreciate the unwisdom of this attitude, and we still hope that the Minister will take the wider view of national needs and possibilities, and so secure the willing services of the main body of general practitioners of all types.

The case of the Insurance Acts Committee, the constitutionally authorized executive of the insurance practitioners and of the whole British Medical Association in this matter, is that for many months past it has been trying to cultivate friendly relations with all concerned in the insurance service, including the representatives of approved societies, that it has suggested or accepted remedies for all those defects of the service which were considered important, and that for such a service, in its national and individual aspects, no fee less than the 9s. 6d. at present given can be justly offered. If the arbitration award of 11s. in 1920 is taken as just, it is difficult to see how any sum less than 10s. 4d. should be paid in present conditions; but this is not insisted on, although no argument in the Minister's reply shakes the conclusion reached. Viewed in another way it is found that the fees derived from private practice or from much non-State contract practice among the classes of society

from which insured persons come alike compare favourably even with the present capitation fee. The acceptance of 8s. 6d. would necessitate a standard of living appreciably lower than that of pre-war times, even expressed in its lowest terms, and without regard to the effects of increased taxation. It is certain that the lowering of the fee would have its reaction on the rewards of all branches of professional work; and this fact, together with the other questions of freedom from approved society dominance, and of avoiding any set-back to the development of an insurance medical service which will be worthy of the profession and of the nation alike, constitutes a situation which must be viewed with grave concern and which calls for united and immediate action.

The reasoned reply by the Insurance Acts Committee to the Minister's offer (SUPPLEMENT, October 6th, p. 149) is printed in this week's SUPPLEMENT (p. 161). The matter is now in the hands of the Local Medical and Panel Committees, which will send representatives to a Conference to be held in London on October 18th. At that Conference most important decisions must be taken. There is little time to secure a satisfactory adjustment; but we hope that the Minister of Health may yet be able to make some further move that will enable a full, contented, and nationally useful service to be established.

### PELLAGRA.

We publish this week an account, illustrated by photographs on a special plate, of two cases of pellagra recently observed in the Hospital for Sick Children, Great Ormond Street, by Drs. Robert Hutchison and Donald Paterson. The disease appears to have been more commonly observed in Italy than in other countries; it was recognized there first as a distinct disorder early in the eighteenth century, and still prevails to a considerable extent. It has been observed also in France, Portugal, Austria, Hungary, Rumania, Macedonia, Egypt, and in some parts of the North of France. In the British Isles a case was recognized by Brown as long ago as 1860; another case was noticed by Cranston Low in Scotland in 1909; and in 1913 two cases were reported in our columns by Dr. C. R. Box from St. Thomas's Hospital. His paper was illustrated by coloured plates (1913, vol. ii, p. 2) showing the appearance of one of the patients and the histology of the nervous lesions described by Sir Frederick Mott in a paper also published in that issue. The two patients were brothers, and both died. The family had resided first of all at Leyton in Essex, afterwards at Catford (within the Metropolitan area), and later at Slough, Buckinghamshire. In 1914 Dr. Box recorded another case in our columns (vol. ii, p. 397); this patient also was a child, and the disease appears to have begun at the age of 1 year and 8 months, while she was residing at a village in Yorkshire. Of the two patients whose cases are now recorded by Drs. Hutchison and Paterson, one had lived in a village near Ipswich and at Walthamstow, Essex; the other at Acton, Middlesex—districts which can both be described as within the confines of Greater London.

The writers of the paper published this week state that their main object is to draw the attention of clinicians in this country to the fact that pellagra is really endemic in England. As the diagnosis, except in typical cases seen during the spring and summer months, or when the rash is well marked, is not easy,

pressure exerted on the cord from within the upper dorsal spine. The operation has been undertaken as an attempt which have failed to respond to conservative treatment. A thorough trial is given to conservative treatment before the operation is undertaken. The operation consists in splitting the dura mater of the affected vertebra with a fine needle and removing the contents of the spinal canal above and below the site of the lesion. Whittman's frame is used to hold the patient in a prone position. Improvement of the paralysis follows the operation. Four cases are reported. The operation was successful in all cases and permanent. The spinal fluid was found to be normal in all cases.

293. Treatment of Tuberculous Peritonitis by Laparotomy and Heliotherapy

M. TAYLOR, M.D., and J. H. HARRIS, M.D.

July 10th, 1923. (J. Clin. Med., 1923, 2: 1041.)

Laparotomy combined with heliotherapy is described as a method of treating tuberculous peritonitis.

The authors report on the results of this treatment in a series of cases.

The results are described as follows:

1. The appetite returns.

2. The weight increases.

3. The abdominal pain disappears.

4. The tuberculous process is arrested.

5. The patients are able to return to their normal activities.

6. The mortality is low.

7. The treatment is simple and easy to perform.

8. The results are permanent.

9. The treatment is suitable for all ages.

10. The treatment is suitable for all stages of the disease.

11. The treatment is suitable for all types of tuberculous peritonitis.

12. The treatment is suitable for all cases of tuberculous peritonitis.

13. The treatment is suitable for all cases of tuberculous peritonitis.

14. The treatment is suitable for all cases of tuberculous peritonitis.

15. The treatment is suitable for all cases of tuberculous peritonitis.

16. The treatment is suitable for all cases of tuberculous peritonitis.

17. The treatment is suitable for all cases of tuberculous peritonitis.

18. The treatment is suitable for all cases of tuberculous peritonitis.

19. The treatment is suitable for all cases of tuberculous peritonitis.

20. The treatment is suitable for all cases of tuberculous peritonitis.

21. The treatment is suitable for all cases of tuberculous peritonitis.

22. The treatment is suitable for all cases of tuberculous peritonitis.

23. The treatment is suitable for all cases of tuberculous peritonitis.

24. The treatment is suitable for all cases of tuberculous peritonitis.

Ophthalmology.

Tourney's Reaction.

P. G. DOYLE, M.D. (J. Clin. Med., 1923, 2: 1041.)

The reaction is described as follows:

1. The reaction is a positive reaction.

2. The reaction is a negative reaction.

3. The reaction is a doubtful reaction.

4. The reaction is a positive reaction.

5. The reaction is a negative reaction.

6. The reaction is a doubtful reaction.

7. The reaction is a positive reaction.

8. The reaction is a negative reaction.

9. The reaction is a doubtful reaction.

10. The reaction is a positive reaction.

11. The reaction is a negative reaction.

12. The reaction is a doubtful reaction.

13. The reaction is a positive reaction.

14. The reaction is a negative reaction.

15. The reaction is a doubtful reaction.

185. Effect of Blood Transfusion on the Results of

Perniciou Anæmia.

HAROLD L. GROSS, M.D. (J. Clin. Med., 1923, 2: 1041.)

The results of blood transfusion are described as follows:

1. The results are positive.

2. The results are negative.

3. The results are doubtful.

4. The results are positive.

Obstetrics and Gynaecology.

Tuberculosis and Pnenapno.

287

The results of treatment are described as follows:

1. The results are positive.

2. The results are negative.

3. The results are doubtful.

4. The results are positive.

5. The results are negative.

6. The results are doubtful.

7. The results are positive.

8. The results are negative.

9. The results are doubtful.

10. The results are positive.

11. The results are negative.

12. The results are doubtful.

13. The results are positive.

14. The results are negative.

He fed rabbits for about six months on the ordinary diet (tofukara), to which fresh meat was added. No renal symptoms or microscopical changes in the kidneys resulted. At the end of the period the meat was withheld, whereupon the appetite gradually diminished, the animal wasted, Oedema was a frequent symptom, and there was an increased tendency to infection. Microscopically the kidneys showed swelling of the epithelium of the tubular epithelium. In addition there was hyaline degeneration of the capillaries of the glomeruli. Suzuki is of opinion that the nephritis was the result of derangement of the general metabolism of the body due to the abnormal diet, and that the similar disease in man is probably due to analogous metabolic changes. Kusano describes experiments bearing on the influence of an excess of nutrient material on the liver. Six series of experiments were carried out: (1) feeding with cane sugar (30 to 60 grams daily) for prolonged periods (30 to 135 days), and (2) for shorter periods (2 to 65 days); (3) feeding with glucose; (4) feeding with casein (15 to 50 grams); (5) with peptone; and (6) with casein and cane sugar combined. In all of these experiments atrophic cirrhosis of the liver resulted; there was a deposit of fibrous tissue at the periphery of the lobules, together with parenchymatous degeneration of the epithelium, the two changes being, in the author's opinion, independent of each other. Kawamura and Kazama, following up a previous observation that the young of rabbits infected with *Schistosoma japonicum* showed evidences of rickets, found that the disease could also be produced by injecting the parasite directly into the bones of animals. Both macroscopic and microscopic evidences of rickets were present, and the calcium content of the bones was reduced. Generally a complete cure resulted in about a hundred days; it was hastened by the administration of thyroid powder. Miyagawa has studied the toxic action of the cells of the alimentary mucous membrane in relation to the formation of gastric ulcer. He was able to produce iso-gastrotoxins and iso-enterotoxins, by means of which ulceration of the digestive tract could be induced; similarly with regard to auto-gastrotoxins and auto-enterotoxins. The formation of cytotoxin varies in different individuals, and the susceptibility of normal animals to the cytotoxin varies also. In addition to their direct action in producing ulcers, the author considers that the cytotoxins hinder the healing of ulcers arising from other causes. An enterotoxin or hepatotoxin will at times produce a gastric ulcer, but not with the same degree of certainty as gastrotoxin.

#### SCIENTIFIC AND INDUSTRIAL RESEARCH.

THE Report of the Committee of the Privy Council for Scientific and Industrial Research for 1922-23, shows the far-reaching importance of the work carried on under the auspices of this Committee. The civil departments concerned in public administration, it is noted, are making larger use of the machinery now existing for the scientific attack upon problems that affect them. As part of the policy of co-ordination, periodic conferences have been held between representatives of the Department of Scientific and Industrial Research, the Development Commission, and the Medical Research Council, at which the biological secretary of the Royal Society has been present. These conferences, the report states, have provided valuable opportunities for the consideration of such matters as the responsibility for the conduct of investigations at borderlines, the possibility of co-operative action in the conduct of investigations in which more than one of these depart-

ments may be interested, and the continuance of research work which has developed in such a way as to bring it outside the scope of the fund originally aiding it. These discussions have helped to define the common problems of human and animal disease, and have emphasized the interdependence of biological and physical research. They have driven home to the Committee the conviction that a national policy in research, complex though it might be and directed by diverse and suitably designed organs, must be conceived and implemented as a unity. A series of conferences were held during the year with the management of the British Empire Exhibition, and a departmental committee was appointed to consider how science and the application of science to industries could best be represented. It was agreed with the exhibition authorities that they should appoint a small committee, nominated by the Royal Society, to assume responsibility for the organization of the central scientific exhibit, and a larger committee, acting on behalf of the research associations, to deal with the general organization of sectional scientific exhibits. With regard to the plea that was made in last year's report that a vigorous search for new knowledge and the more effective application of science to industrial processes offered a potent means of re-establishing our country and maintaining its population, it is recorded with satisfaction that in December, 1922, an Act with a similar end in view was passed in France, creating a national office for scientific and industrial researches and invention in connexion with the Ministry of Public Instruction. The report includes a summary of the work of the various research boards and committees of the Department of Scientific and Industrial Research. At the National Physical Laboratory, in addition to the researches which it necessarily undertakes in the discharge of its primary functions as the custodian of national standards, with a view to the improvement of measurements of all kinds, including those relating to standards of quality, much research work of a general character is carried out. It includes researches involving continuous observations over a very extended period of time, and researches requiring the use of exceptionally expensive equipment or other special facilities—for example, work at very high voltages or at very low temperatures. The Food Investigation Board dealt with varied problems affecting fruit, meat, fish, and eggs; many of these have been noted in our columns. Among new investigations which are being carried on are the design of a commercial gas store for fruit, the growth and respiration of fungi under various conditions, the autolysis of meat and of fish, the bacteriology of fish, and the freezing point of eggs in relation to the risk of overcooling. A report from the Oxygen Committee, shortly to be published, contains descriptions of the improvement of the known method of handling liquid oxygen and liquid air on a practical commercial scale: of these methods the Committee has been principally concerned with the development of the double-walled vacuum vessel as a container. Among the other boards and committees carrying on different branches of research work are the Fuel Research Board, the Geological Survey Board, the Radio Research Board, the Physics, Chemistry, and Engineering Co-ordinating Research Boards, the Fabrics Co-ordinating Research Committee, the Adhesives Research Committee, and the Lubrication Research Committee. During the academic year 1922-23 the Committee made 403 grants to research workers and students in training; of these 252 were allowances to students to enable them to take advantage of the facilities offered by various universities and colleges or other research institutions, 33 were personal grants to research workers to undertake independent research or to act as scientific assistants.

THE KING.

"On a Staples Mattress the essentials of organs, spine and limbs is avoided."

"By prevention of sagging, distortion of organs, spine and limbs is avoided."

Staples Mattress cannot sag—digestive organs undistorted—Result: Better health, nerves soothed, better sleep.

THE BRITISH MEDICAL JOURNAL

Oct. 13, 1923.]

associated with a high or low infant mortality, and in any social situation the complex poverty and the complex infant mortality both needed to be investigated before it was decided what were the factors at work in a particular instance. The chief difficulty in mass statistics was to segregate from a number of coincident factors the factor which was under investigation. It was because Farr saw the difficulty so clearly and endeavoured to provide for it in the public work he did that his name was held in such high honour by statisticians and among those interested in public health. Sir Arthur Newsholme paid a tribute to Farr's mathematical genius, and mentioned that he was one of the two members of the Institute of Actuaries. His work had been extended by his successors, notably by Dr. T. H. C. Stevenson, and the appreciation of the value of vital statistics as an instrument of research, a guide to sanitary effort, and a means of public enlightenment, was becoming widespread. The function of statistics was to sum up many individual experiences in a single statement. Among the causes of error the personal equation of the observer himself in the selection and use of data was of importance, and it might be necessary to remain satisfied with a qualitative interim judgement, although this in some cases was as likely to be erroneous as an attempted quantitative judgement. Inadequate evidence could never be made more complete by continuing to scrutinize it. As an illustration of the pitfalls of statistics he quoted the official report issued in 1920 giving the results of the physical examination for military service of 2,500,000 men in the eleven months ending October, 1918. Of these men over 10 per cent. were found permanently unfit for military service. Unduly pessimistic inferences had been drawn from these figures. He agreed that what the figures disclosed was a serious state of affairs, but before accepting implicitly the percentages for each of the four grades into which the men were divided it was necessary to have some assurance that the physiological standards applied were appropriate and uniform. Could mass statistics be trusted which were gathered at examinations by a large number of different medical boards all over the country working in very different circumstances of leisure and adequacy? The men who were examined were those left over after the fittest men of the nation had already enlisted. Another illustration of possibly erroneous deduction from statistics concerned the figures relating to crime in certain family stocks; from these figures the inheritance of criminal instincts was sometimes deduced, but was there not such a thing as moral contagion? Again, it was generally stated that one-third of all prostitutes were feeble-minded, with the apparent implication in the control of the feeble-minded of prostitution consisted in the control of the feeble-minded. But before this became a practical policy it must be ascertained by examination of successive random samples from the social groups from which prostitutes were derived whether the percentage of mental defect among prostitutes was in reality greater than in these random samples; he believed that this would be found not to be the case. While pointing out these and other limitations in the applicability of certain classes of statistics, he welcomed the increasing use of statistics in public health work, and the help which statistical experts could give to the solution of the many public health problems still outstanding. Lord Eustace Percy, Parliamentary Under Secretary to the Ministry of Health, who presided, said that the audience would carry away from the lecture certain necessary cautions with regard to the use of vital statistics. He mentioned the tests for mental deficiency applied to men offering themselves for enlistment in the United States Army during the war, the results of which had been quoted to suggest a ludicrously high proportion of mental defect in

the American population. He did not think that the results could be taken as a general indication of intellectual capacity, or that they need arouse apprehension in any quarter. At the same time, statistics brought out significant facts; one to which public attention should be directed at the present moment was that while the infant mortality rate was falling the puerperal death rate was not falling.

#### MUSEUM DEMONSTRATIONS.

THE course of museum demonstrations open to advanced students and medical practitioners at the Royal College of Surgeons of England (Lincoln's Inn Fields) began on Friday, October 12th, when Sir Arthur Keith, F.R.S., the conservator, gave the first of three demonstrations on hernial formations. In this he dealt with acquired hernial formations at various points of the alimentary canal. In the second demonstration, to be given on Friday, October 19th, he will deal with hernial formations of developmental origin which occur along the alimentary and respiratory tracts; and in the third, on Friday, October 26th, he will discuss the distinction between congenital and acquired forms of true hernia. Three demonstrations will also be given by Professor Shattock, F.R.S., pathological curator, on Mondays, beginning on October 15th, when he will deal with necrosis. The second demonstration on October 22nd will be on arteries, and the third on actinomycosis and Madura disease. All demonstrations will begin at 5 p.m.

#### THE INSURANCE SERVICE AND THE MINISTRY OF HEALTH.

IN last week's SUPPLEMENT we published the reply of the Minister of Health to the statement by the Insurance Acts Committee regarding the remuneration of insurance practitioners from 1924 onwards. This week we publish the rejoinder by the Insurance Acts Committee, which, it is hoped, will be read not only by insurance practitioners but by the profession generally. The present issue of the SUPPLEMENT contains also the reply of the Minister of Health regarding the proposed changes in the Regulations, and in order that the circumstances may be fully understood we follow it with a summary of the position as to the proposed alterations. Lastly, we publish the final reply of the Insurance Acts Committee on this matter to the Minister, in which attention is drawn to various points upon which agreement has not so far been reached.

THE gold medal of the Royal Society of Medicine will be presented to Dr. F. Gowland Hopkins, F.R.S., Sir William Dunn Professor of Biochemistry in the University of Cambridge, at a social evening of the Society, to be held on October 30th at 8.30 p.m. At 9 p.m. Professor Hopkins will deliver an address on stimulants of growth.

THE munificent gift made by the Rockefeller Foundation to University College, London, and its Medical School will not have been forgotten. It has been, however, long understood that the Foundation did not intend to limit to London the financial assistance it would give to medical educational institutions in Great Britain. We understand that the Foundation has for some time been making inquiries in Edinburgh, and is about to provide the cost of a clinical research laboratory there; it is also considering the endowment of a chair in clinical surgery.

SIR JOHN BLAND-SUTTON, President of the Royal College of Surgeons of England, will take the chair at the first Victor Horsley Memorial Lecture to be delivered in the Barnes Hall of the Royal Society of Medicine by Professor Sir Edward Sharpey Schafer, F.R.S., on Thursday, October 25th, at 5 p.m. Admission to the lecture is free.

THE WISDOM OF THE BODY:

The Harveian Oration,

DELIVERED BEFORE

THE ROYAL COLLEGE OF PHYSICIANS OF LONDON

ON ST. LEON'S DAY, 1923,

BY

ERNEST HENRY STARLING, C.M.G., M.D., LOND.,

SC.D. (HON.), D.V.M., M.D. (HON.), BRISTOL,

PROFESSOR OF PHYSIOLOGY OF THE ROYAL SOCIETY,

FELLOW OF THE COLLEGE.

"Who hath put wisdom in the inward part? or who hath given understanding to the heart?"

MR. PRESIDENT AND FELLOWS OF THE COLLEGE.—We are met here to-day to celebrate our annual feast, founded by the immortal Harvey with the twofold purpose of promoting mutual love and affection among ourselves and of commemorating the famous men who, by their works, have benefited the College. This is our day of All Saints, when we canonize in our memory and record our indebtedness to not only those who have assisted our work by material gifts, and leaders of successive generations in the science of medicine, but also all those of any race or profession on whom the mantle of Harvey has fallen and who, following his injunction to our Fellows and Members, to "study out the secrets of nature by way of experiment," have enlarged the bounds of science and increased the powers of our art.

It is customary and right in this our annual oration to begin by calling to mind the work of the Founder himself, and especially the great discovery of the circulation of the blood, which represents the beginning and the foundation of all that we know in physiology and medicine. Harvey's treatise on the Motion of the Heart is throughout so modern in spirit, so akin in conception and treatment to records of research of the present day, that we may easily fail to appreciate the stupendous advance in human physiology that it embodies, and to wonder that we have had to wait so long for the full fruition of Harvey's discovery. But it must be remembered that the world knows the line in advance of the race, such an outpost must remain more or less in the air and incapable of further advance until the whole line has moved up to its support. We now know that many of the problems raised by Harvey, on the progress of other branches of human knowledge, and that is why to-day in our minds and memories we are reckoning among our saviors not only the distinguished names of Harvey, Hales, Cavendish, Lavoisier, Bernard, Pasteur, and most of others, who were only in spirit our colleagues and most of whom were not even students of medicine, succeeding Harvey's work, the whole scientific world has been travelling in order that medicine might be born, and this is that our science has had to wait until our own mind in his dream of the results of his discovery.

"Finally, reflecting on every part of medicine, physiology, pathology, therapeutics, when I see how many questions can be answered, how many doubts resolved, how much obscurity illustrated, by the truth we have declared, the light I might proceed so far, and expatiate so widely, that this my tractate would not only swell out into a volume, which would not only be a purpose, but my whole life, perhaps, would be consumed for its completion."

by the great clouds of ignorance which had still to be dispersed. But the advance of knowledge, though slow at first, has progressed with ever-accelerating speed. When I compare our present knowledge of the workings of the body, and our powers of interfering with and of controlling those workings for the benefit of humanity, with the ignorance and despairing impotence of my student days, I feel that I have had the good fortune to see the sun rise on a darkened world, and that the life of my contemporaries has coincided not with a renaissance but with a new birth of man's powers over his environment and his destinies unparalleled in the whole history of mankind.

Not but there is still much to be learned; the ocean of the unknown still stretches far and wide in front of us. But for its exploration we have the light of day to guide us; we know the directions in which we would sail, and every day, by the co-operation of all branches of science, our means of conveyance are becoming more swift and sure. Only labour is required to extend almost without limit our understanding of the human body and our control of its fate.

HARVEY'S GREATEST GIFT TO THE WORLD.

The great gift which Harvey gave to us was, indeed, not his discovery of the circulation of the blood, but his method of discovery. There is no evidence that the age-long duration of the period during which man had striven and striven to defend himself and to procure his food, the long delay in the discovery of the workings of bronze and later of iron, are to be ascribed to any mental inferiority of those men as compared with those of the present day. What was lacking was the method. Man had advanced by fits and starts as the result of discoveries which were probably accidental, and these discoveries spread gradually along the lines of commerce and culture by imitation and the right copying of ritual. But with the realization of the possibilities of the method of experiment—that is, the creation and repetition of a chosen experience under controlled conditions, such as we find in its full development in Harvey's treatise—man came almost at a bound into the full use of his brain capacities which he had evolved during a long struggle for existence against the warring forces of an inhuman nature.

It is true that the ultimate goal and the biological justification of science is the improvement of human conditions; but for the full and untrammeled exploration of the advance of the experimental method it is essential that more than the causes and cure of disease, but the nature of Nature. This implies that we are to give free scope to the spirit of curiosity, with some measure of self-restraint, at any rate in his youth (is endeavor). We must have a part of the order of Nature and of the things that are contributory to the science of medicine.

Since this was the spirit that actuated Harvey, it is evident that his choice of the subject of the heart was not the completion of the work upon which he has given the world a new chapter in the history of medicine. It is clear that his choice of the subject of the heart was not the completion of the work upon which he has given the world a new chapter in the history of medicine. It is clear that his choice of the subject of the heart was not the completion of the work upon which he has given the world a new chapter in the history of medicine.

## OPENING OF THE WINTER SESSION.

accomplish much useful work on behalf of the mentally defective. Thus while the accommodation existing when the Act came into operation was about 3,000 beds, at the present time there is accommodation for 19,262. The summary of mental defectives under care shows that on January 1st, 1923, they numbered 15,786; compared with the numbers on the same date a year before there is a total increase of 1,976. As the report states, the increase in the numbers would no doubt have been materially greater had not the local authorities been informed that, owing to the pressing need for economy, only "urgent" cases should be dealt with. Much useful work is being done in providing supervision for those defectives who, for economic or other reasons, cannot be sent to institutions. At the beginning of the present year there were 9,854 defectives under statutory supervision, and in this connexion the Board refers very favourably to the work being done by the Central Association of Mental Welfare in establishing occupation centres for defectives who live at home. The Board is of opinion that the regular occupation and training afforded by this form of supervision will tend to reduce the number of cases who will ultimately have to be sent to an institution.

The report includes interesting details connected with the administration of mental hospitals and various suggestions for their improvement. We have thought it well, however, to emphasize more particularly the incidence of insanity in our midst because this is a matter of vital concern to the community as a whole.

## OPENING OF THE WINTER SESSION.

## WESTMINSTER HOSPITAL.

The annual dinner of the past and present students of Westminster Hospital was held at the Trocadero Restaurant on Thursday, October 4th, when 116 were present, with Mr. Walter Spencer, the senior surgeon, in the chair.

In giving the toast of "The Westminster Hospital and Medical School," Mr. Spencer reminded his audience that Westminster had the distinction of being the first hospital entirely supported by voluntary contributions, and had now entered on its third century of existence in the neighbourhood in which it was founded. The voluntary system had persisted throughout and there was, he felt, every prospect of a continuance if the appeal shortly to be made to meet the cost of rebuilding was successful. The new building would have 235 beds and there were to be new special departments, operating theatres, and improvements of every kind which experience had shown to be necessary. In giving the toast Mr. Spencer coupled with it the name of Dr. A. S. Woodwark, the Dean of the Medical School, to whose indefatigable efforts he paid a generous tribute.

Dr. Woodwark in his reply described the condition of the school as satisfactory in every way. Each year since the war had witnessed a steady increase in the number of students, a succession of examination pass lists which compared well with those of any other medical school in the metropolis, and a gradual return to pre-war conditions as regards social and athletic activities. Although the medical school was carrying on efficiently, if under difficulties in the present circumstances, he hoped to see the culties in the present circumstances, and on completion the hospital reopened was £50,000, and the cost of renovation would satisfy the most fastidious. Sir James Purves-Stewart proposed "The Universities." They had, he said, the exceptional privilege of entertaining that evening the Regius Professors of medicine of Oxford and Cambridge, the Vice-Chancellor of London University, and the Dean of the Medical Faculty of the University of Cardiff, so that the oldest universities and the youngest were represented. All were closely in touch with Westminster through members of the staff and students. With personal reminiscences, Sir James Purves-Stewart identified each of those representatives with the toast.

In his reply, Sir Archibald Garrod gave a brief but fascinating résumé of the relation of biochemistry to clinical practice. Sir Clifford Allbutt addressed himself particularly to the present-day students and drew an optimistic picture of the possibilities open to those who preferred to devote themselves to the more academic side of their profession. Mr. H. J. Waring said that the solicitude of London University was not so much as regards the size of the medical school as the quality of the work it achieved, and congratulated Westminster upon its efficiency as indicated by examination results. Professor David Hepburn pointed out that although they had their own qualifications in Wales they liked to regard the degrees and diplomas obtained in the metropolis as a kind of post-graduate finish. A considerable number of their students had passed through Westminster with reciprocal satisfaction.

Mr. William Turner proposed "The Past and Present Students," adding that this was generally the most popular toast of the evening, but superseded on this occasion by that of the Chairman, to come later, to whose retirement he referred in sympathetic terms. He coupled with the toast the names of Dr. Robert Nimmo Watson, who had most patriotically come all the way from Harrogate, and Mr. R. A. Hickling. Dr. Watson, in a much appreciated speech, ably voiced the sentiments of the men in general practice who had known Mr. Spencer throughout the whole of their career and had found every year more reasons to express their gratitude. Mr. Hickling, in representing the present students, said that the only thing to complete their satisfaction would be the provision of an athletic ground of their own.

Mr. Arthur Evans, in proposing "The Visitors," said that besides the distinguished guests from the universities they were happy to welcome, among others, the Head Master of Westminster School, Mr. H. Costley-White; the Head Master of St. Paul's School, Dr. Hillard; the Chairman of Master of Epsom College, Mr. Arnold Powell; the Secretary, Mr. C. the Hospital, Sir Edward Pearson; the Secretary, Mr. C. Power; the Architect, Mr. Percy Adams; and Dr. Eric Marshall, who would be remembered as one of Sir Ernest Shackleton's party. He coupled with the toast the name of the Rev. Harold Costley-White. Mr. Costley-White expressed his very great pleasure at being entertained by the hospital, with which he was so closely associated and for whose kind services he had abundant reasons to be grateful. As a schoolmaster, he regarded a medical education as a very liberal one, and a medical career as an ideal for which he had always felt that a boy required a very early preparation psychically as well as academically. Dr. de Havilland Hall, with many affectionate references, proposed "The Chairman," his old colleague now retiring from the staff of the hospital, which he had served so loyally for thirty-five years. Mr. Spencer briefly replied.

## CHARING CROSS HOSPITAL.

The annual dinner of past and present students of Charing Cross Hospital was held on Wednesday, October 3rd, at Gatti's Restaurant, with Dr. T. Watts Eden in the chair. The toast of "The Hospital and Medical School" was proposed by Mr. Peter Daniel, who commented upon the fact that the medical school, having welcomed women students during the war, had no intention of shutting its doors upon them; the women students had added to the strength of the school. Dr. W. J. Fenton, Dean of the Medical School, who replied to the toast, said that the position gained by the school in recent years had been well maintained; the number of students at present was 170, and 33 had qualified during the past twelve months. The health of "The Guests" was proposed in felicitous terms by Sir Herbert Waterhouse, and replies were made by the Right Hon. Sir Donald Maclean, M.P., Sir Humphry Rolleston, President of the Royal College of Physicians, who told a Scots story, and Professor Walter W. Chipman, professor of obstetrics in McGill University, Montreal. Professor Chipman said that Canada was proud to act as a liaison between the old country and America. He contrasted the hospital dinner with the "Year Dinners" in Canada, which were run entirely by the

the course of the disease or delaying its fatal issue. It is interesting to note that these advances are the direct outcome of researches made with the sole object of elucidating the intimate nature of muscular contraction. In his book Harvey remarks: "Of these things we shall speak more opportunely when we come to speculate upon the final cause of this motion of the heart." Such speculation at that time would have been in vain. It seems probable that he anticipated finding the solution in the study of the generation of the final cause of the action either of skeletal muscles into the final cause of the action of the heart. He knew of the heart requires a physical and chemical knowledge which even now we are only beginning to attain. I would remind you that the string galvanometer, the employment of which has thrown so much light on the essential nature of disturbances in the heart rhythm, was invented by Einthoven with a view to studying the electrical changes accompanying activity in any kind of tissue.

#### THE INHERENT CONTRACTILE POWER OF THE HEART.

In dealing with the origin of the rhythmic power of the heart Harvey rightly ascribes it to the heart muscle itself, and brushes aside any suggestion that it is dependent on the nervous system, or the liver, or any other organ. His assurance on this point was due to his observation of the developing chick, in which the first sign of life was the pulsating spot of blood in the region where the heart was being formed. It is interesting to note that it is the same method—namely, the investigation of development—which has settled the question of the seat of the rhythmic power of the heart and has revealed to us the origin and course of the rhythmically recurring wave of contraction in the heart of man. By means of a technique, first devised by Harrison in the United States, it is possible to cultivate living tissues outside the body, in much the same way as we have learned to grow micro-organisms. Using great care to exclude infection, we are able to transfer to a glass slide fragments of tissue which, being kept warm, live and multiply. From such a preparation further generations can be brought up, and in one such case a preparation of the muscle cells of the heart of a chick has been kept alive, growing and dividing, for twelve years, a time far beyond the natural span of the life of the fowl. Such a result proves that mortality is but an accident of the complexity of our living machine and not a necessary quality and fate of the tissues of which the body is composed. But during these twelve years the muscle cells have not ceased to contract rhythmically, showing that in their peculiar properties must be sought the origin of the rhythmic beat of the heart, thus finally disposing of the various views which have been held, according to which the origin of the heart beat was to be sought in the nervous ganglion cells and fibres present in different parts of this organ.

And it is by the embryological method—that is, by observing the processes of generation—that Keith and Plack were able to lay the anatomic foundations of our present knowledge of the origin and course of the contractile processes in the heart of the higher animals. In the developing heart, as in the lower vertebrates, the beat originates in that part of the contractile tube which later will form the sinus venosus. In the course of the changes undergone during development, Keith showed that this sinus tissue persisted at definite parts of the mature heart and could be distinguished under the microscope from the surrounding parts of the heart. This special sinus tissue was given the name of the sino-articular node and the articulo-ventricular node.

#### The Cardiac Cycle.

The brilliant experiments by our distinguished fellow, Sir Thomas Lewis, have resulted in a complete knowledge of the part played by these nodes in the cycle of the heart's contraction. He has shown how the sino-articular node is the pace-maker of the heart, how the contractile process originating here spreads through the auricular

you will remember that Harvey insists on the essentially secular nature of the heart. "It was not without good grounds," he says, "that Hippocrates in his book *De Medicina* ascribes it to a muscle; as its action is the same, so its function, namely, to contract and move something increasing dilatation of the heart means increased length of its muscular fibres, so that we can express it as a relation between length and energy—the longer the muscle fibre the greater the energy its contraction. In this form we find that the law of the heart is that of all muscular tissue, whether voluntary or involuntary. The Swedish physiologist Blix showed us years ago that the energy evolved in the contraction of a frog's muscle was proportional to its initial length, and A. V. Hill has proved that this holds good for heat production during activity, and therefore for the action and recovery of the muscle. So that in searching for the cause of the heart's power of adaptation we are brought into the region of final causes, in which we associate function with structure, and see in muscular contraction the expression of molecular changes occurring on the surface of longitudinal fibrillae. Thus we bring together in one formula the sum total of our experience with regard to the nature of excitation itself, development of mechanical energy, and the chemical, critical, and heat changes which accompany muscular contraction. We are still far from a complete understanding of these matters, and still farther from any possibility of reconstructing a muscle fibre. But the path, far as we can see along it, seems to lead to no impassable barrier, and to promise a complete description of the nature of excitation and contraction as molecular events occurring at surfaces.

#### THE LIMITS OF ADAPTATION.

Is there any limit to this power of adaptation? In skeletal muscle an increase in the length of the muscle fibres leads to an augmentation of the energy changes of contraction, succeeded later by a diminution as the muscle becomes over-tired. In the healthy mammalian heart the limits are by the strength of the muscle fibres themselves. Freed from the pericardium, we find the heart goes on increasing its contraction with increasing dilatation, and when the muscle fibres are actually ruptured; and when the heart finally fails we find its substance beset with haemorrhages. In the body this overstretching of the heart is prevented by the tough fibrous sac of the pericardium. When a demand on the heart is so great that the heart dilates to its limits of the pericardium, any further dilatation and therefore increased strength of beat becomes impossible; the heart therefore falls off, and in the whole animal this diminished output results in defective supply of blood to the muscles and brain, giving rise often to fainting and at any rate enforcing complete rest. Further activity of the animal becomes impossible, and the heart is automatically given less work to do, so that it is in a necessary condition of the animal to recover, unless the increased activity of the animal's continued survival, as in a fight to the death. In this case when the heart comes up against the pericardium the fight is finished and the animal succumbs, and the same story in the terminal changes of heart failure and the process of compensation which I have described above becomes insufficient. Here again enforced rest may give time and opportunity for re-establishment of sufficient circulation, but with advance of the fundamental condition, even complete rest becomes powerless to save the heart: the output falls off, the circulation is insufficient for the needs of the tissues, and we get all the secondary results of failure of compensation—suppression of urinary secretion, waterlogging of the body, and malnutrition of all its organs which usher in the fatal termination. During the last few years great advances have been made in our knowledge of the causation of many of these morbid conditions, and this increased knowledge has, as always, enhanced our powers of dealing with such cases, of staying

train the "contrôleur" of each railway coach questions personally each passenger and any cases of suspected illness are noted; passengers are also questioned as to any illness they have noticed among others. There is also a medical inspection at each big railway junction. Attached to stations where inspection takes place are hospitals and disinfection plants for dealing with cases of actual illness and with suspects.

I can testify from my own observation that railway stations and railway carriages are kept clean and tidy. I travelled from Moscow to Minsk, a twenty-seven hours' journey, on an ordinary slow train and had many opportunities of getting out at wayside stations, to get meals or buy papers or just walk about, and all were in excellent order. The food was good and cheap, though served in a somewhat rough and ready way; most stations had on sale different kinds of white bread, chicken, sausages, meat of various kinds, eggs, milk, lemonade, bottled beer, chocolate, etc. Little children sold fruit, chiefly apples. Drinking water is provided at most stations, and at many hot water is provided for making tea.

The first-class carriages were fitted as four-berth sleeping compartments; I had a compartment to myself most of the way, and the conductor made me tea whenever I wanted it. No bedding was provided (bedding is provided, however, on the express trains and the wagons-lits), but the carriages were quite as clean as those on the Polish side of the frontier and were certainly better lighted at night. From Minsk to the Polish border (a three hours' journey) I travelled in a third-class coach with wooden seats and no upholstery of any kind. The paint was ancient but the coaches were clean.

A factor in the improvement of the sanitary condition of the country is undoubtedly the general return towards normal which is a marked feature of Russia at the present time. For with this there goes an improvement in the moral of the population and so of their cleanliness. The peasants also, despite high taxation, are on the whole better off than they were, and considerable numbers of new houses are being built in the villages. But the largest share is probably to be put down to the sanitary campaign of the Commissariat of Health, which, under the leadership of Dr. Semasko, has carried its propaganda and organization from one end of Russia to the other. This organization is particularly noticeable on the Volga, where each vessel coming from the south has to moor at a sanitary quay (which is provided everywhere) and each passenger is questioned closely about himself and about others. It is an effective system of mass inspection which supplements notification of illness by the officials of the vessel concerned. The control of persons leaving Russia is also very strict; only certain frontier points are allowed to be used legally, and evasion is difficult and hazardous. At each point it is necessary to present a certificate that the person has been examined for (a) typhus fever, (b) relapsing fever, and (c) cholera.

Large epidemics other than those already mentioned do not exist—the number of cholera cases has been less than 100 for the whole of Russia during this year, and although there was (August, 1923) a small epidemic of plague, about 100 cases, near Tsaritsin, which is close to the endemic centre in the Steppes, it is at present strictly localized.

Among other important factors which have helped in the control of the epidemics it is necessary to mention first the Epidemic Commission of the League of Nations, acting through Dr. Haig and Dr. Panteleoni, which has played an important part. The executive and organizing ability of these two officers and the existence of an office at Moscow have undoubtedly been of the greatest service to Russia.

Another helpful factor was the work of the American Relief Association, which in addition to aiding the relief of the famine on a very large scale, helped also in the equipment of hospitals all over the country, so that numbers of institutions are still carrying on their work with materials supplied by the American Relief Association. Indeed, practically every relief unit of every nation did some more or less medical work and contributed some medical supplies.

The return to the normal, previously referred to, has been largely helped by the opening up of free trade within the country. But the political fact must not be forgotten that the possibility of organization within the country or of help from without has only been possible on any extensive scale since the cessation of military intervention against the Bolsheviks and the opening up of diplomatic and trade relations with foreign countries, which dates (effectively) only from the beginning of 1921. The medical work accomplished up to the present, therefore, has been largely done during the last two and a half years, a fact which makes its success the more remarkable considering the heritage of disorganization and even of military destruction—as of railway lines and bridges for instance—with which the sanitary administration has had to grapple. In this work not only have the doctors worked heroically, very many unfortunately having died at their posts, but the Communist party, the rulers of Russia, have supplied personnel to do some of the more terrible and dangerous sanitary services, such as cleaning out towns encumbered with corpses and filth. Very few doctors in Russia are Communists; but, politics apart, it must be recognized that in the ranks of that party there have been found men and women with the cold 2 a.m. kind of courage that has enabled them to face the danger of almost certain death from infectious disease, when carrying out the more horrible and dangerous tasks in a great sanitary campaign, and not when acting as principals but as subordinates.

Now that the louse-borne epidemics have been controlled the mosquito-borne epidemic is to be tackled. At present almost all equipment is lacking and the supply of quinine is quite inadequate; it is estimated that 20,000 kilograms of quinine hydrochloride are required at once.

The groundwork for the antimalarial campaign is, however, already laid, as, apart from the general medical service which works efficiently and devotedly, there are 250 doctors who have attended special antimalarial courses organized by the Epidemic Commission of the League of Nations, and in October of this year another 100 will have completed their course. Part of this course is given by Russian doctors, professors of universities, and specialists, and part by medical men from other countries. Representative men from France, Italy, Czecho-Slovakia, and Germany have already taken part in this work, but up to date no one from England.

The amount of typhus and relapsing fever recorded in June is probably that normal for the country, and not to be completely removed until the social conditions of certain endemic centres in Moscow, Petrograd, and other large towns can be changed. The effort to make these changes is now being made and will probably be successful in a few years' time. Meanwhile the problem of malaria remains one of urgent importance, and the statistics here show an unfortunate increase in illness on a large scale. The mortality is also very high, in the absence of quinine or other methods of treatment, and it is even stated to amount to 40 per cent. of cases attacked in some places. The severe forms of malaria occur in the Caucasus and the South, but there is much malaria in other towns. Fortunately, that in Moscow is of a mild type.

Beyond the question of malaria there looms up the question of syphilis and of tuberculosis. Tuberculosis is said to be more than twice as prevalent now as before the war; but syphilis in some districts affects 80 per cent. of the total population, and its treatment must be a matter of years.

A harvest of disease still to be reaped will accrue from the after-effects of the famine in the southern parts of Siberia. The actual famine is now over and relief measures are no longer required. But there are still places where food conditions are not good, and there are all the results of deprivation still remaining among the survivors of the famine which will only become fully apparent in the course of some years. Of the general effects of conditions in Russia on the health of the population it is too early to speak, but it is already clear that, while many peasant villages have not been largely affected, the residents in the towns have been subjected to a very great strain, under

## INTEGRATION OF FUNCTIONS.

In the multiplicity and diversity of the physiological effects produced by these various chemical messengers are apt to lose sight of the fact that we are here investigating one of the fundamental means for the integration of the functions of the body. These are not merely interesting facts which form a pretty story, but they are pregnant with possibilities for our control of the processes of the body and therefore for our mastery of disease. Already medical science can boast of notable achievements in this direction. The conversion of a stunted, pot-bellied, blavering cretin into a pretty attractive child by the administration of thyroid, and the restoration of normal health and personality to a sufferer from Graves' disease by the removal of the excess of thyroid gland, must always impress us as almost miraculous. In the same way we may cure or control for the time being diabetes insipidus by the injection of the watery extract of the posterior lobe of the pituitary body. The latest achievement in this direction is the preparation by Banting and Best in Canada of the active principle normally formed in the islets of the pancreas, and the proof that the diabetic condition in its severest forms can be relieved by its subcutaneous administration.

## THE INTERACTIONS OF HORMONES.

In my Croonian Lectures I asserted that if a mutual control of the different functions of the body be largely determined by the production of definite chemical substances in the body, the discovery of the nature of these substances will enable us to interpose as any desired phase in these functions, and so to acquire an absolute control over the workings of the human body. I think I may claim that, in the eighteen years that have since elapsed, we have made considerable progress towards the realization of this power of control which is the goal of medical science. But there still remains much to be done and many difficulties to be unraveled, and it may be worth our while to consider along what lines researches to this end must be directed. There are no doubt many hormone relationships of which at present we are unaware, but every year research adds to their number. But assuming we know that such and such an organ produces an internal secretion which is necessary for the normal carrying on of a given function of functions, we may desire to diminish or enhance its effects in a patient or to replace it when it seems to be entirely lacking. There seem to be three possible methods by which we medical men can interpose our art in the hormone workings of the body.

## I.

In the first place we may find what is the effective stimulus to the production of the hormone, and, by supplying this, increase its production by the responsible cells. For instance, we know that by the administration of acid, or at any rate by increasing the passage of weak acid from the stomach to the duodenum, we can enhance the production of secretin and so of pancreatic juice and the other juices. Probably, therefore, when we give dilute acids to assist gastric digestion, we are setting into motion the whole chain of reflex processes in the alimentary canal, and the chief value of our administration may be its effect on the pancreas. But in a large number of cases we do not yet know what is the effective stimulus to the production of these internal secretions. In the case of the adrenals we know the secretion can be augmented through the central nervous system and the sympathetic nerve under the influence of emotions or of lack of oxygen, but we have no knowledge of the factors determining the production of the pituitary hormones or of insulin by the islets of Langerhans, and this condition of ignorance extends to most of the other ductless glands. In some cases deficient production of a hormone may be due to the absence from the food and drink of some necessary constituent. Thus iodine is essential to the formation of the specific secretion of the thyroid gland (iodothyria).

Just few years that definite proof has been brought forward showing that these effects are due to the removal of chemical messengers normally produced in the testes. The whole differentiation of sex, and the formation of secondary sexual characters, are determined by the circulation in the blood of chemical substances produced either in the germ cells themselves or, as seems more probable, in the interstitial cells of the testis and ovary, which themselves are probably derived from the germ cells of the embryo. Thus it is possible by operating at an early age to transfer male into female and vice versa. Removal of the ovaries from a hen causes the assumption of male plumage; the removal from a young cock of the testes and their replacement by the implantation of ovaries cause a disappearance of the comb and the assumption of the plumage of the hen. Each animal as concerns its general build and colour has a neutral form, which, as has been shown by Pizzardi, results from the extinction of either testes or ovaries. In fowls the neutral form, as judged by the plumage, approximates the male, whereas in sheep the neutral form resembles the female. There is no question that, by the implantation of ovaries or testes into the foetus at a sufficiently early age, one could produce the whole development of the internal and external genitalia corresponding to the sex of the gland implanted. It is worthy of note that these sex characters affect also the mentality and the reactions of the animal, although they are quite independent of any nervous connections. Here, as in the case of the thyroid, the functions of the central nervous system in their highest manifestations depend on the circulation in the blood of chemical substances or hormones. The wonderful development that takes place in the female after conception to fit her to nourish the foetus as well as the young child, is also due to hormones, produced in some cases perhaps in the ovaries, in other cases in the product of conception itself.

## The Hormone of the Adrenal Medulla.

We owe to Scharrer the knowledge of the internal secretion of the medulla of the suprarenal bodies. As Cannon has pointed out, this secretion is poured into the blood during conditions of stress, anger, or fear, and acts as a potent reinforcement to the energies of the body. It increases the tone of the blood vessels, as well as the power of the heart's contraction, while it mobilizes the sugar bound up in the liver, so that the muscles may be supplied with the most readily available source of energy in the struggle to which these emotional states are the essential precursors or concomitants.

## The Pituitary Hormones.

Wonderful, too, is the influence exerted by the secretions of the pituitary body. This tiny organ, which was formerly imagined to furnish the mucus to the nasal cavities, consists of two lobes which have different internal secretions. That produced by the anterior lobe seems to influence growth, excess producing gigantism or acromegaly, while deficiency leads to retarded growth and infantilism. The posterior lobe, which in aspect would seem but a small collection of nervous parts of the body. They are contraction of the two distinct substances; they may increase or diminish the flow of urine; they affect the excretion of chlorides by the kidney; and, according to Krogh, their constant presence in the blood is essential for maintaining the normal tone of the capillaries. In the frog the post-pituitary hormone is responsible for the protective adaptation of the colour of the skin to the environment, an adaptation which is effected by retraction or expansion of the pigment cells or chromatophores of the skin; and if we may accept Kammmerer's conclusions, the pituitary hormone which is poured into the blood for this purpose affects the germ cells themselves, so that individuals born of parents that have lived in light or dark surroundings are correspondingly light or dark—a real transmission of acquired peculiarities, effected not by the germules of Darwin, but by the influence of a soluble diffusible hormone on the germ plasma.

apply to the District Nurses' Association to supply one of their nurses, who would, in case of an outbreak, nurse in the hospital and would nurse the sick in the district at other times. This would provide the very necessary service of district nursing in Belmullett, and at the same time an hospital staff for emergencies. The Board of Health would pay the nurse's salary, board, etc., which would cost £150 10s. to £163 a year.

Whether the hospital is to be in its present position long or short, the roof must be patched and the gutters repaired, and also fire grates put in all the rooms. The Board of Health will also require to get tenders for driving the ambulance, and provide some sort of shelter for it.

The board decided to adjourn further consideration of the report and, in the meantime (1) to ask the military to evacuate the workhouse, and (2) to appoint a ward maid at £40 a year and rations.

## Correspondence.

### THE PROBLEM OF SUCCESS FOR MEDICAL WOMEN.

SIR,—Will you allow me very briefly to refer to one paragraph in the interesting address delivered by Sir Humphry Rolleston at the London (Royal Free Hospital) School of Medicine for Women on October 2nd? I do so at his request.

In considering the problem of success for medical women, he stated that "in 50 per cent. or more of women the monthly rhythm is a distinct handicap." Now happily the more rational life lived by women to-day has so altered the incidence of pain and malaise during menstruation that, whatever may have been the fact in the past, recent investigation shows that a very small minority of women suffer from any such disability.

Miss Wiltshire, M.Sc., published in the *Lancet* of August, 1921 (p. 388), the results of observations on basal metabolism and oxygen consumption, showing no monthly change.

Dr. Hollingworth of Columbia University made careful observations on men and women with the object of observing any effect which menstruation might have in women on speed of movement, steadiness of hand, accuracy of perception, and association of ideas. The result was that no inefficiency in practical or mental work could be detected, during the menstrual period, as compared with other parts of the cycle, nor was fatigue more readily induced at that time.

Dr. Sanderson Clow, in a paper published by the *BRITISH MEDICAL JOURNAL* on October 2nd, 1920, gives useful guidance in the rational treatment of adolescents during menstruation, and shows that the percentage of girls in a large college who suffered no pain or disability of any kind was increased from 73 to 85 per cent. when baths and usual exercises were continued throughout the period. In only 2 per cent. was serious disability present.

I may refer those interested in the subject to Dr. Chisholm's article in the *Encyclopaedia of Midwifery and Diseases of Women* (Oxford Press) and to the chapter on menstruation in *Womanhood and Health* by Dr. Christine Murrell.—I am, etc.,

FLORENCE E. BARRETT.

London, W.1, Oct. 9th.

### BETEL CHEWING AND CANCER.

SIR,—The letter of Mr. R. L. Spittel on the relationship between betel chewing and cancer of the cheek (*BRITISH MEDICAL JOURNAL*, October 6th, p. 632) is both valuable and welcome. Hitherto the data necessary for establishing a causal relationship between them have been disappointingly meagre. As far as my reading goes, no estimate of the prevalence of this cancer has yet been offered, and in spite of repeated interrogation of medical friends who might have a first-hand knowledge of its occurrence I have failed to elicit good evidence. For all we know to the contrary epithelioma of the inside of the cheek might be no commoner in betel chewers than in other populations not addicted to the practice. And for that reason I ventured to advise caution in accepting a proposition which, personally, I was far from denying.

Mr. Spittel's rough estimate of its frequency dispels that hesitation. May I respectfully urge him to communicate at

greater length his experience of betel-chewer's cancer? The age incidence, its frequency as disclosed by hospital or other records, its latent period, its precancerous forms, and its course are some of the important points on which he can speak with unquestionable authority.—I am, etc.,

ARCHIBALD LEITCH.

London, S.W., Oct. 6th.

SIR,—Mr. R. L. Spittel's letter on "Betel chewing and cancer" (October 6th, p. 632) raises the question of the source of cancer infection. Those who, like myself, do not accept the theory of irritation as a cause of cancer will look for some source of infection of the irritated region. Is the betel not put into the mouth by a hand contaminated by soil? Is the irritated penis not infected by a hand contaminated by soil? In this country is the irritated lip not infected by a contaminated hand of the man who labours on the land? Is alimentary cancer of the stomach and intestine not a result of infection from food handled by an imperfectly washed hand, such as that of a gardener?

All domestic animals and birds are liable to cancer of the alimentary tract. Soil contaminated by them or by human beings may contain the infective organism, which finds its resting place on an irritated surface. Soil is, of course, not the only thing which may harbour the infective organism. My point is that we must not concentrate too much on the "irritation." There is something else to which the irritation is only a handmaid.—I am, etc.,

JOHN CAMPBELL.

Delfest, Oct. 6th.

### THE TREATMENT OF TUBERCULOSIS BY THE SPAHLINGER METHOD.

SIR,—I notice a letter from Dr. George W. Cheater in the *JOURNAL* of September 29th (p. 585) asking if the cases published by Dr. L. Williams in a recent issue are the only ones treated by the Spahlinger serum or vaccine. As I have just returned from Geneva, where I spent several weeks with M. Spahlinger, and had every opportunity afforded of visiting his institution at Carouge and seeing and examining many cases, may I point out that there are authentic records of over 400 cases treated, with 80 per cent. recoveries. Many of them were advanced cases, regarded as hopeless. The most remarkable fact in connexion with them is the permanency of the results. I saw and examined cases treated in 1913 and 1914 who are now quite well, following their ordinary occupations, and exhibiting no trace of disease. Prejudice seems to exist in the minds of many members of the profession from the fact that M. Spahlinger is not a medical man, and from a suspicion that these serums and vaccines are in the nature of secret remedies. There is no secrecy; any member of the profession who will go to Geneva and visit the laboratory, as several very eminent men have already done, will be courteously received, and be able to see the preparation of the serum and examine cases. M. Spahlinger—who, by the way, has never charged one half-penny for any of his serum or vaccine, notwithstanding the fact that he has had several very tempting offers, amounting to several hundred thousand pounds, from commercial interests for the sole right of producing and distributing his remedies—hopes, as soon as he has produced a sufficient quantity of serum and vaccine to demonstrate its efficacy, to publish the whole of his methods for the benefit of suffering humanity.—I am, etc.,

THOMAS WATTS, M.D., M.P.

Manchester, Oct. 9th.

### COLOSTOMY AFTER TRANSPLANTATION OF URETERS.

SIR,—I agree with Sir Thomas Myle's letter (September 15th, p. 486) that incontinence of urine "causes distress to both mind and body." He advocates transplantation of the ureters, in this condition, into the rectum, and, on account of the risk of infection of the kidneys, recommends a complete colostomy to be performed, the rectum being shut off to act as a reservoir for the urine.

Even though there is a risk of infection of the kidneys after transplantation of the ureters, which I do not dispute, in my opinion it would be better to run this risk

permanent service in that country at increased rates of pay and pension. Probably by these means sufficient officers would be obtained for Indian necessities, and the remainder of the corps, after one tour in India, would have little foreign service.

Whether these views are accepted or not, it is high time that some steps were taken to alleviate the undoubted hardships of the officers of the R.A.M.C., who at present, while enjoying few compensating advantages, have more frequent moves and more foreign service than any other branch of the army.—I am, etc.,

October 5th.

FIELD OFFICER.

### Obituary.

SIR FREDERICK BRADSHAW, K.C.B., M.R.C.P.,  
Major-General A.M.S.(ret.).

MAJOR-GENERAL SIR ALEXANDER FREDERICK BRADSHAW, K.C.B., K.H.P., Army Medical Service (retired), died suddenly at Oxford on September 27th, aged 88. A month ago, on the occasion of the marriage of his daughter to Lieut.-Colonel Stewart Gordon, he was knocked down and injured by a motor car.

He was born in London on December 5th, 1834, the son of Mr. G. Bradshaw, of the Inland Revenue Department, and was educated at St. Bartholomew's Hospital, taking the L.S.A. in 1856 and the M.R.C.S. in 1857. He entered the army as assistant surgeon in 1857, attained the rank of surgeon major-general on March 10th, 1891, and retired on March 10th, 1895. For the first eight years he served in the Rifle Brigade, 2nd Battalion, with which he took part in the suppression of the Indian Mutiny, serving at the siege and capture of Lucknow, for which he received the Mutiny medal with the clasp for Lucknow. In 1863-64 he was garrison surgeon at Delhi, and in 1865 was posted to the Chestnut troop of the Royal Horse Artillery. In 1869 he was appointed surgeon to the commander-in-chief in India, Sir William Mansfield, afterwards Lord Sandhurst; and continued to hold that post under the two succeeding commanders-in-chief, Lord Napier of Magdala and Sir Frederick Haines. On the staff of the last named he served in the Afghan war of 1879, receiving the medal. From 1884 to 1886 he was principal medical officer of the Quetta division, and in that capacity served as P.M.O. in the Zhob expedition on the north-west frontier of India in 1884, when he was present at the action at Hamza village, and was mentioned in dispatches. The frontier medal was not granted for this campaign. In 1886-87 he served as P.M.O. of the Frontier Field Force in Egypt, after which, for a short time, he held the post of P.M.O. of the northern district in England. From 1887 to 1892 he was again in India as P.M.O. of the Rawal Pindi division, and with that division served as P.M.O. in the Hazara campaign of 1891, when he was mentioned in dispatches in the *London Gazette* of October 20th, 1891, and received the frontier medal with a clasp, and the C.B. From his promotion to surgeon-general till his retirement he held the appointment of P.M.O. of H.M.'s forces in India, the second post in the service, next to that of director-general. He was appointed honorary physician to the Queen in 1899, and promoted to K.C.B. in 1912. He was also a F.R.G.S., and in 1882 had taken the M.R.C.P.Lond.

After his retirement he settled in Oxford, where he did much public work, as honorary secretary of the Oxford Eye Hospital, as member of the Oxford Town Council, and as a member of the committee of the Warneford Asylum. He became a Fellow Commoner of Worcester College in 1897; the university gave him the honorary degree of M.A. in 1900, and the full degree of M.A. in 1910. During the late war he acted as honorary consulting physician to the military hospitals in Oxford. He edited a memoir of Katherine Grace Loch, R.R.C., who was chief lady superintendent of Queen Alexandra's Military Nursing Service for India. In 1864 he married Ellen, daughter of Colonel R. S. Ewart, Bengal Army, and had three sons and five daughters. His youngest son was killed in the late war. The other two sons are Lieut.-Colonel F. E. Bradshaw, D.S.O., late Rifle Brigade, and Colonel C. R. Bradshaw,

Indian Army. His daughters are Lady Lennox-Cunningham, O.B.E., Mrs. Cecil Kekewich, Mrs. Hunt, wife of Professor A. S. Hunt of Oxford, and Mrs. Stewart Gordon. His remains were cremated at Golders Green on October 2nd, a funeral service being held at the same time at St. Margaret's Church, Oxford.

### Universities and Colleges.

#### UNIVERSITY OF LONDON.

A COURSE of eight lectures on the histology of the nervous system is being given by Dr. C. da Fano (Reader in Histology in the University) at King's College (Strand, W.C.2) at 4.30 p.m. on Wednesdays. The first lecture was given on October 10th.

A course of eight lectures on new aspects of nutrition is being given by Professor V. H. Mottram, M.A., at King's College for Women (61, Campden Hill Road, W.8) on Mondays at 5 p.m. The first lecture was given on October 8th. Admission to these courses is free, and attendance on them is recognized in connexion with the B.Sc. (Honours) Degree in Physiology.

The newly elected Jodrell Professor of Physiology, Dr. A. V. Hill, will give a public inaugural lecture on the present tendencies and future compass of physiological science on Tuesday, October 16th, at 5.30. The lecture will be held in the theatre of the new anatomy building at University College. Professor E. H. Starling will take the chair. Cards of admission will be sent on application to the secretary of the college: such an application should enclose a stamped addressed envelope. The new anatomy building will be open to inspection as from 4.30 that afternoon.

#### UNIVERSITY OF SHEFFIELD.

THE Diploma in Public Health has been awarded to Samuel Bryson and Patrick Kane.

#### UNIVERSITY OF ST. ANDREWS.

THE following candidates have passed in the examinations indicated:

FIRST M.B., CH.B.—Organic Chemistry: B. W. Anderson, Agnes C. Cunningham, J. W. L. Dickson, W. J. Frazer, A. Thornton, R. O. Whyte. Inorganic Chemistry: B. W. Anderson, R. O. Whyte. Botany: T. Thornton. Physics: J. A. Blain, Adewale Osherty, J. Feldman, Victoria M. Willoughby.

Latin: A. P. R. Borrowman, Barbara T.

Leslie, Ena M. Liddell, S. McManus, Robertson, B.Sc., Janet O. Morrison, J. R. C. R. Baxter, T. F. Black, Ellen Do. J. Blair, Jennie P. Laird, Victoria R. L. Leslie, Murray, P. C. Robertson, Gertrude J. Sturrock. Midwifery: Moanawar Khan Afridi, C. R. Baxter, T. F. Black, N. T. Brown, W. F. Dorrard, B.Sc., L. Farrell, A. A. Finnigan, A. Henderson, Lillian A. M. Johnston, B.Sc., Luttur Rahman Khan, G. D. Laing, Jean R. Mason, J. R. Miller, N. Nelson, P. C. Robertson, Jalnti Dass Sakser.

FIRST D.P.H.—Physics and Meteorology: Frances Heron-Watson, J. Lambertson.

#### ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

AT the monthly meeting of the Royal Faculty of Physicians and Surgeons of Glasgow held on Monday, October 1st, the following were admitted, after examination, as follows:

Ch.B., B.Sc., D.P.H. (Glasgow): John Aitken (Leicester), Alexander Reginald Lester, Colin William McRury, M.D. (Manitoba), Manuel Joseph Ealdanza, M.B., D.S. (India).

A copy of the bronze medal, struck in commemoration of the octocentenary of St. Bartholomew's Hospital, has been presented to the Faculty by Dr. Alexander Macphail, Ministry of Health, London.

### The Services.

#### NAVAL MEDICAL COMPASSIONATE FUND.

AT the quarterly meeting of the directors of the Naval Medical Compassionate Fund, held on October 9th, the Medical Director-General of the Navy, Surgeon Rear-Admiral Joseph Chambers, C.B., C.M.G., in the chair, the sum of £44 was distributed among the several applicants.

#### DEATHS IN THE SERVICES.

Dr. John Robert Stevenson Robertson, of Hayling Island, Hants, died suddenly in London on September 26th, aged 64. He was the second son of the late Alexander Robertson, J.P., of Berwick-on-Tweed, and was educated at Edinburgh, where he graduated as M.B. and C.M. in 1881. In 1883 he entered the army as surgeon and served in the Sudan campaign of 1885, taking part in the expedition up the Nile and across the desert for the relief of

cases disappointing. Hofmeister, for instance, having made

These disappearing B vitamins, for instance, having been added to rice meal in a preparation which certainly contained a curculline base, but nothing else which gave evidence from a relatively large amount, obtained from further attempts of Casimir Funk ended in a similar way. The base proved quite inactive. The much-mooted possibility of a purely chemical synthesis of such complexity, and there exists no classical techniques for their solution. Maybe we shall have to replace the familiar use of selective solvents and precipitants by some new technique. Some have felt that there may be hope in the adoption of physical methods such as electrical transport, or in the use of selective adsorbents, in the lines of Willstätter's current endeavours to isolate enzymes. Vitamins would seem to be considerably more tractable than enzymes, and the work done in attempts to purify them has encouraged at any rate a faith that the problem will be solved. I have already ventured some opinion that we shall not have to wait very long before the constitution of one or other of them is known.

The clear differences in function exerted on specific lines. The results have indeed been clear that the influence of each is from the first by differences in their directness. In studies of metabolism, however, it is well to remember that the chemical events in the organism are not so much as they are more or less isolated experiments. No one process in the body can be regarded abnormal without ultimate effects upon the whole organism. Since there is a harmonious co-ordination of the body as an organized whole. For an organism to survive and reproduce requires that the various parts work together in a coordinated manner. If the results are considered they will show in respect to the experiments required. If the results are considered they will show in respect to the experiments required.

in the hope of discovering the seat and mode of action

which has been demonstrated by others in the case of the constituents of diets, and which E. Melnany recently insisted upon in the case of still other constituents, the hope of discovering the true nature of the problem does not seem to be far off.

At a meeting of the Society of Superintendents of Tuberculosis Institutions to be held at 122, Harley Street, at 4 p.m. on Monday, October 15th, a discussion on thoracoplasty will be introduced by Mr. W. H. C. Romanis, F.R.C.S., and a report from the committee which has been considering the question of the training of tuberculosis nurses will be presented.

A MEDICAL Prayer Union meeting will be held, by invitation of Dr. Mary Scharlieb, at 149, Harley Street, W.1, on Thursday, October 25th. An address will be given by Mr. Rendle Short, F.R.C.S., on evolution in relation to Christian principles. An intimation of intention to be present will be welcomed by the honorary secretary, Dr. Tom Jays, livingstone College, Leyton, E.10.

The method adopted for ventilating the Council Chamber of the London County Council was described at the autumnal meeting of the Institution of Heating and Ventilating Engineers by Messrs. P. M. B. Grenville and T. Moodie. By means of trunks under the chamber an individual supply is provided for each seat. Besides the main inlets, special registers are so arranged to every seat that each member can direct the incoming air either towards himself or vertically out of his range. The plant is capable of delivering 3,000 cubic feet an hour for every occupant of the chamber. The apparatus consists of a humidifier, heating batteries, and fans automatically controlled from the chamber itself, and means of forced circulation of hot water to over two thousand radiators, having a total heating surface of 68,349 square feet. The hot-water supply to over eight hundred lavatory basins and sinks is capable of providing 71,400 gallons of hot water in an hour.

ACUTE poliomyelitis was made a notifiable disease in all the communes of the province of Rome on September 4th. From July 23rd to August 15th 103 cases of plague were notified in Egypt; 7 occurred in Port Said and 4 each in Alexandria and Suez.

DR. HERMANN DOLD has succeeded Professor Uhlenhuth as director of the Behring Institute of Experimental Therapeutics at Marburg.

OWING to financial conditions forty-five hospitals were closed in Prussia during 1922, including nine private hospitals, with 1,049 beds in Berlin alone.

MESSRS. WATSON AND SONS (Parker Street, Kingsway, W.C.2) have issued a new bulletin describing the x-ray combination horizontal couch, vertical screening stand, and high-tension transformer which they manufacture.

A PRELIMINARY summary of the vital statistics for 1922 of Prince Edward Island, Nova Scotia, New Brunswick, Ontario, Manitoba, Saskatchewan, Alberta, and British Columbia has been published. The average birth rate of these Canadian provinces was 28.8 per 1,000, compared with 26.3 in the previous year; British Columbia had the lowest birth rate, 18, and New Brunswick the highest, 29.2. The average infant mortality rate was 86.6, ranging from 64.6 in British Columbia to 103.7 in New Brunswick. The average death rate at all ages was 10.4 per 1,000, compared with 10.6 in 1921; of the deaths 75 per 1,000 were due to cancer and 68 to tuberculosis.

## Letters, Notes, and Answers.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitology Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, Mediscera Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin) and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

"X. Y." would be glad of any references to literature dealing with sterility following mumps oophoritis.

VITAMINS AND CHLOROPHYLL.  
"J. R." (London).—Vitamins B and C occur regularly in substances free from chlorophyll. There is no reason to suspect any relation between them and chlorophyll. Vitamin A is nearly always found associated with chlorophyll. Pure chlorophyll, however, contains no vitamin A. There is a possibility that vitamin A is a substance related in some way to chlorophyll. It may be that the presence of chlorophyll aids its formation.

### INCOME TAX.

"CAECUM" sold some war stock in June, 1922, and for the year to April, 1923, returned for assessment half a year's interest. The inspector of taxes says he is liable to be charged tax on a full year's interest—that is, on the amount of interest received in the previous year, that being the basis of assessment for untaxed interest.

\* \* The inspector's statement is correct as far as it goes. If, however, when "Caecum" sold out the war stock he did not then hold and did not acquire during 1922-23 stock of identical or similar nature, he appears to be entitled, under Sec. 34 of the Income Tax Act, 1918, to have the assessment for 1922-23 reduced to the amount of the untaxed interest for that year—under the principle laid down in *Brown v. The National Provident Institution*.

### Car Transactions.

"H. T. M." bought a second-hand motor cycle in 1921 for £110 (new cost £135); he sold it in 1923 for £65, buying a new car for £256.

\* \* The total expenditure of (£256 - £65 =) £191 was partly an outlay of capital by which an improved vehicle was obtained, and "H. T. M." is entitled only to that part which represents the cost of replacing his cycle with one similar in make and condition to the cycle as it was when he purchased it—that is, to £110 - £65 = £45.

### Book Debts.

"A, B, and C" have been assessed as partners on the basis of cash receipts; the inspector has now intimated that book debts should be included.

\* \* Unless there is some special reason for the request—as, for instance, if "A, B, and C" have taken over a part or the whole of another practice—we do not think that the inspector's attitude is likely to be sustained on appeal before the local commissioners if "A, B, and C" resist his request. Where the gross receipts of a practice are more or less constant the amount of the actual cash receipts must approximate closely to the correct value of the gross bookings. For this reason cash receipts have for many years been accepted as the basis for income tax returns, even in those cases where the bookings were falling (as during the war) and the cash receipt basis therefore worked against the taxpayer. In these circumstances, and in view of the great difficulty in estimating the value of any given amount of bookings, "A, B, and C" may reasonably resist the inspector's action and appeal to the commissioners (local or special) with reasonable prospect of success if he refuses to give way.

### LETTERS, NOTES, ETC.

MR. H. JESSOP of Burnley, whose advertisements have often appeared in our pages in recent years, asks us to suggest to practitioners who dispense for their patients that this is the time to order their winter supply of dispensing bottles.

DIFFICULT LABOUR DUE TO FOETAL SPASTICITY.  
DR. C. H. S. HORWITZ (Streatham, S.W.) writes: Mrs. P., a primipara, aged 32, gave birth to a full-time child on September 29th. Calculating from the first day of her last period she was about three weeks overdue. Her measurements were normal, and an x-ray photograph showed that there was plenty of room for the head to pass into the cavity of the pelvis. The head of the child remained above the brim until labour commenced. There was an undue amount of liquor amnii. Labour proceeded quite satisfactorily until the head reached the perineum, where it remained for several hours in spite of good pains. So I decided to apply forceps, and a small amount of chloroform was administered. The head was easily extracted, but I experienced the greatest difficulty in delivering the rest of the body, which seemed so rigid. Upon the birth of the child there was a post-partum haemorrhage of some severity and difficult to control. The child was somewhat blue, and held its body in a condition of opisthotonos. It soon cried and continued to do so almost continuously for twenty-four hours. There was evidently some meningeal irritation, with the left side of the body affected than the right. The rigid condition of the child's body with marked head retraction, would account for the difficulty I had experienced in delivering it. The pupils were equal and reacted to light, but there was slight ptosis of the left lid. Vertical nystagmus was present. There was marked rhythmic twitching of both arms and hands, more violent on the left side. The thumbs were strongly flexed and adducted; the elbows and wrists were flexed. The legs were spastic, but to a less extent than the arms, and the feet were flexed. The child died about forty-eight hours after birth. No post-mortem examination was held.

### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 33, 34, 35, 38, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 36 and 37.

The refractory period is a period of time during which the neuron is unable to fire again. This is due to the fact that the membrane potential is still below the threshold level. The refractory period is divided into two parts: the absolute refractory period and the relative refractory period. During the absolute refractory period, the neuron is completely unable to fire, no matter how strong the stimulus. During the relative refractory period, the neuron can fire, but only if the stimulus is strong enough to overcome the hyperpolarization that has occurred. The refractory period is an important feature of neurons because it ensures that the signal is propagated in one direction only.

*The Action of Drugs and Poisons on the Synapses*

The first of these is the fact that the sympathetic nervous system is a part of the autonomic nervous system, and is therefore under the control of the brain. The second is the fact that the sympathetic nervous system is a part of the autonomic nervous system, and is therefore under the control of the brain. The third is the fact that the sympathetic nervous system is a part of the autonomic nervous system, and is therefore under the control of the brain.

stimulating action is exerted by acropine upon many ganglionic nerves, but it is not so rapid. It is also found that the action of acropine upon the nerves of the sympathetic system is selective and is in the first place upon certain synapses, and its local application to the ganglion is experimentally ascertained by the effects of the preganglionic fibres. After painting the ganglia with a weak solution of acropine the sympathetic nerves are rendered incapable of conduction, whereas the blood vessels, stimulated by nicotine, injected into the blood vessels, stimulate the receptive substance of muscle so that the muscles enter into a state of contraction. Curare has the reverse effect and paralyzes the receptive substance of voluntary muscles so that the muscles enter into a state of relaxation. It is interesting to note that the action upon the receptive substance of the sympathetic nervous system is selective and is exerted upon certain portions only of a functional synapse, as an example of a chemical material which exerts a selective influence. Adrenalin, a chemical material which exerts a stimulatory action, and these drugs have been called by Dargatzis "sympathomimetic," because on injection into the blood they bring about effects which resemble those produced by stimulation of the sympathetic nerves.

meals the milk and cream should be continued hourly. This treatment should be continued for one year, the alkalis being gradually diminished. The author records the results in 28 cases (13 of ulcer of the stomach; 3 of ulcer of the duodenum, 12 of hyperacidity). In 5 they were negative; in 23 good or brilliant. In 10 of the 23 successful cases improvement followed immediately; in 13 gradually. On examination two to twelve months after leaving the hospital only 4 of the 23 cases remained free from symptoms. These had continued the treatment for a long time—two to twelve months; 9 patients who had continued the treatment for one to six months were not quite free from symptoms, but felt much better than before the treatment; 5 patients who had continued the treatment for only one to three months suffered from a recurrence of the symptoms. Sippy's treatment is strongly recommended, especially in chronic cases associated with gastralgia. It should be continued for several months, if possible for a year; and Orlanski advises that it should always be tried before operation is undertaken.

## Surgery.

### 277. Tuberculosis of Vesical Diverticula.

DUVERGEY (*Journ. d'Urologie*, July, 1923, p. 1) records the cases of bladder diverticula infected by tuberculosis so far reported in the literature, together with one of his own. He has found two undoubted cases of tuberculous infection of a diverticulum, one of which, his own case, involved a diverticulum arising from the urachus. A third case showed the diverticulum arising from the bladder, but of a true bladder involvement, not of a true bladder diverticulum, a typical inguinal cystocele; whereas the fourth case, a typical bladder diverticulum arising from the left wall of the bladder, though infiltrated and ulcerated, was not shown pathologically to be definitely tuberculous. He finds that the condition in bilateral renal tuberculosis. He finds that the condition in question is rare; it invades the diverticulum by extension from a vesical lesion following a primary renal infection. It is only by means of the cystoscope that diagnosis can be made. As the infection of the diverticulum coexists with other tuberculous lesions of the genito-urinary system, treatment is limited to intradiverticular lavage and instillation. Palliative surgical treatment—drainage of the diverticulum—is only indicated in the presence of such complications as severe infection and retention. The author considers that the drainage should be direct (diverticulostomy), but in cases in which the diverticulum is not directly accessible it should be indirect (transvesical) after a preliminary cystotomy.

### 278. Operations for Inguinal Hernia under Local Anaesthesia.

J. C. BLOODGOOD (*Amer. Journ. of Surg.*, August, 1923, p. 185) considers that this operation can be performed with as great a certainty of success under local anaesthesia, and with far less risk to the patient, as with a general anaesthetic. He employs 1/4 per cent. solution of novocain as the local anaesthetic. The patient is put on a light diet before the operation, and he finds the majority do better without the hypodermic injection of morphine. The line of incision is infiltrated subepidermally until it stands out like a large hive. After its division the aponeurosis is infiltrated and divided. The other structures are similarly treated as they become exposed. The sac is isolated and opened and its contents reduced, and the sac is then closed with a suture. The closure of the wound follows and is usually painless. The author does not transplant the cord, but sutures the sheath of the rectus muscle and internal oblique to Poupart's ligament. Where there is obliteration of the conjoined tendon it is advised that the cord should be transplanted. The healing of the wound after local infiltration is not as perfect as with general anaesthesia, but any breakdown is usually confined to the skin and fat and has no influence on the result. The advantages of local anaesthesia are the elimination of the dangers of general anaesthesia, and the period of convalescence is shorter. For success it requires considerable experience and practice.

### 279. Living Sutures in the Treatment of Hernia.

W. E. GALLIE and A. B. LE MESURIER (*Canadian Med. Assoc. Journ.*, July, 1923, p. 469) point out that interest in the subject of hernia has recently been aroused by the extraordinary number of recurrences which have developed after operations performed on soldiers during the war. A study of recurred herniae showed that in most instances the muscular and aponeurotic structures which had been sewn together in an attempt to close the abdominal defect had not remained firmly healed together, but had separated to allow the pro-

trusion of another sac. In the hopes of preventing this the authors undertook a clinical and experimental study of the principles underlying the various types of operations. Experiments showed that by scarifying and overlapping the edges of divided fascia and aponeuroses the union was increased, but even this was insufficient when the line of union was subjected to unusual strain. Attempts to reduce the failures following such operations led to the idea of filling the defects in the abdominal wall with pedunculated transplants of aponeurosis or free transplants of fascia lata. This method was abandoned as unsatisfactory, the results being so little improved. It was then decided to overcome these difficulties by the use of living sutures. Sutures of fascia from a rabbit's back behave like ordinary fascial grafts and live practically unchanged. Over catgut and similar sutures they have the great advantage that they are not absorbed and continue for all time to perform their function. This method has been applied to the radical cure of inguinal hernias, many of which had previously recurred after operation. The results have been satisfactory, and no recurrences have been reported. It is useful in all cases of direct hernia and oblique hernia which have recurred after operation. Sutures of fascia lata when used in these cases, if firmly anchored into aponeurotic structures, will permanently close the inguinal canal. Further, when used in large ventral herniae, this type of operation has been most satisfactory in the authors' hands.

### 280. Periarterial Sympathectomy.

A. WOJECIOWSKI (*Lyon. Chir.*, July-August, 1923, p. 421) asserts that the operation of periarterial sympathectomy has now a definite place in surgery. Although the value of this operation is recognized clinically, our knowledge of the physiology of the periarterial plexus is somewhat indefinite. With a desire to elucidate this problem further, the author has carried out certain experimental investigations in order to discover the physiological and anatomical effects produced by the operation. The experiments have been done on rabbits, which animals appear well suited for these procedures. The operation was performed on the carotid and femoral arteries. After noting the results of the operation on the blood vessels the portion of the vessel affected was excised and carefully examined microscopically. The experiments showed that after division of the sympathetic the vessel is contracted below the site of the operation, but the same evening the limb becomes warm and the vessels in the digits are dilated. This continues for one or two weeks, after which it is impossible to distinguish any difference in the temperature or the circulation. In other words, the sympathetic system treated by excision tends to return to the normal after a certain time. At the point where the sympathetic has been divided a scar appears; to avoid the formation of this scar tissue it is necessary to surround the vessel with fat or omentum. These results were obtained in animals and differ somewhat from those found in man; it is, therefore, necessary to study carefully in the future specimens obtained after sympathectomy in the dead subject.

### 281. Camphoric Acid as a Urinary Disinfectant.

E. LIEBMANN (*Schweiz. med. Woch.*, July 12th, 1923, p. 672) has found acidum camphoricum a very useful urinary disinfectant. Its potency in this field has hitherto been overlooked because it has been given in too small doses—that is, 1 to 2 grams. If, however, 3 to 4 grams are given, and in course of the day, its action is much more effective, and the author records in detail 7 cases of infected urine in which complete or almost complete cures were obtained. Most of these cases the acid was urine, and the cystitis and pyelitis were due to coliform bacilli. Good results were, however, also obtained in cases of chronic cystitis, due to such causes as hypertrophy of the prostate, and the results were very satisfactory, although only a quarter of all the cases proved disappointing. In about a quarter of the cases in which it was given, camphoric acid failed, but in these cases salol, urotropine, hexal, and other popular urinary disinfectants also proved useless. On the other hand, there were several cases in which these popular antiseptics failed, and in which camphoric acid was promptly successful. When it causes gastric disturbances, it should be discontinued.

### 282. Treatment for the Paralysis of Pott's Disease.

JOHN FRASER (*Edin. Med. Journ.*, September, 1923, p. 385) comments on the development of paralysis in association with tuberculous disease of the spine as a most disappointing and distressing complication. Months or years may have been spent in the recumbent treatment of the disease when paralysis of the limbs may gradually appear. Spinal paralysis in tuberculous disease develops owing to a localized

## EPITOME OF CURRENT MEDICAL LITERATURE.

is unnecessary also in advanced or malignant cases; in "cicatrical" stationary disease; and in patients whose social conditions admit of prolonged and adequate medical treatment and whose tuberculous disease seems readily susceptible of cure—for example, by artificial pneumothorax. Accordingly bilateral lesions, progressing yet judged still curable, in women of the working classes who are not yet three months pregnant, are those which furnish the best indications for intervention. Tuberculosis before the fourth month of pregnancy is much more likely to be met in medical than in obstetric practice. Intervention should preferably take the form of induction of abortion, hysterectomy being reserved for certain older multiparous women. The vast majority of cases encountered call only for medical treatment, of which probably the most useful form is the induction of pneumothorax.

## Mucous Polypus of the Uterus.

288. ACCORDING to L. MICHON (*Lyon méd.*, July 10th, 1923, p. 583), the discovery of a mucous polypus of the uterus affords good grounds for the suspicion that other morbid gynaecological conditions are present. In young women these consist most frequently in chronic adnexal infection, simple metritis, or cystic or sclero-cystic ovarian degeneration; in middle-aged subjects there is in the majority of cases a coexistent uterine myoma; and in aged patients a mucous polypus may mark the early stages of cancer of the body or carcinoma of the cervical endometrium. In cases in which careful examination fails to demonstrate an associated lesion it is unwise to be content with simple ablation of the polypus, and intrauterine exploration is definitely indicated. The clinical signs of mucous polypus *per se* consist in (1) leucorrhoea, which is continuous and abundant and may lead to pruriginous dermatitis; (2) haemorrhage, which is as a rule slight and intermittent. The polypi are most frequently inserted either just above or below the junction of the cervix and body, or in the fundus in the neighbourhood of the orifice of a Fallopian tube; menstruation or pregnancy may cause a notable augmentation in their size. Histologically their epithelial invagination may be squamous or cylindrical, according to the site of origin, and signs of chronic inflammation are invariably present.

## Sarcoma of the Uterus.

289. AUVRAY (*Bull. Soc. d'Obstét. et de Gynécol. de Paris*, 1923, 4, p. 280) describes three unusual cases of sarcoma of the uterus. In the first a 4-para, aged 36, suffered during six years from menorrhagia, followed by metrorrhagia and fetid intermenstrual discharge and progressive loss of weight. Examination showed a friable vegetating tumour of the cervix and considerable enlargement of the body of the uterus. The pre-operative diagnosis was carcinoma of the cervix and of the body, but microscopical examination of the specimen showed a squamous-celled carcinoma of the cervix separated by a normal zone from a sarcomatous tumour involving the posterior wall of the body. In the second case a nullipara, aged 36, was operated on for a large cystic abdominal tumour of four years' duration, thought to be ovarian. Six litres of chocolate-coloured fluid having been evacuated, the cyst was found to be implanted on the summit of the uterus. Microscopically no epithelial lining was present, and an external muscular layer was clothed internally by oedematous sarcomatous tissue which exhibited intracystic buddings. The third patient showed only of "falling of the womb"; examination showed the vagina to be occupied by a smooth non-ulcerated tumour which had reached as far as the vulva, and appeared to have the characters of a simple hypertrophy of the anterior lip of the cervix. The histological appearances were those of a myosarcoma. This patient, like the second, was apparently well two years after hysterectomy.

## Pathology.

## The Genesis of Renal Tuberculosis.

280. G. SÖDERLUND (*Acta Chir. Scand.*, vol. lvi, Fasc. 1, 1923, p. 27) records four cases of renal tuberculosis which came to operation at an exceptionally early stage. In every case there was a tuberculous cavity situated within a pyramid, evidently constituting the oldest focus. In every case a fistula led from this cavity to the renal pelvis, the whole surface of which showed superficial microscopic tuberculous changes, which were most marked near the opening of the fistula. In none of the four cases was there any tuberculous focus in the parenchyma except a solitary cavity, and in no case was

the renal pelvis free at any point from superficial tuberculous inflammation. The author argues that these cases are remarkably confirmatory of Ekehorn's theory, according to which renal tuberculosis begins as a bacillary embolus in the parenchyma. This embolus gives rise to caseation and cavitation, the process being very slow as long as there is no communication between this cavity and the renal pelvis. Two of the author's cases gave a history and showed signs indicating that the primary haematogenous focus had been latent in the parenchyma for a long time, perhaps for years, being completely shut off from the renal pelvis, and at first causing no other symptom than slight backache. When, however, the disease has extended to the renal pelvis it is probable that it runs a comparatively acute course, for the superficial changes, invariably found by the author in the renal pelvis, were indicative of a rapidly progressive inflammation. This was, indeed, not demonstrable to the naked eye, but the microscopic examination showed typical tuberculous granulation tissue and commencing necrosis.

## Spinal Anaesthesia and Blood Pressure.

291. F. VIRGILLO (*Arch. Ital. di Chir.*, August, 1923, p. 529) states that writers are not agreed as to the effects of spinal anaesthesia on blood pressure, some maintaining that the influence of spinal anaesthesia on the arterial tension is very slight and transient, while the majority are of opinion that during spinal anaesthesia there may be a considerable fall of pressure which may endanger the patient's life. Virgillo, who made observations on forty cases, came to the following conclusions: (1) Spinal anaesthesia carried out with 2 c.c.m. of a 6 per cent. solution of novocain to which has been added a decimilligram of adrenaline per cubic centimetre, and accompanied by subcutaneous injection of 0.25 gram of caffeine, causes a fall of blood pressure ranging from 10 to 20 mm. Hg, and in some cases as much as 100 to 120 mm. The fall of blood pressure is more marked in the case of the maximal than of the minimal pressure. The oscillographic index also shows an almost constant fall. The oscillographic curve assumes the form of a hypotonic or cardiac type. (2) In Virgillo's cases the fall of blood pressure was not accompanied by any general symptoms of an alarming kind. (3) In order to obviate the dangers of the fall of blood pressure caused by intrathecal injection of novocain it is advisable to give subcutaneous injections of caffeine in doses of 0.25 to 0.50 gram two to two and a half hours before the intrathecal injection. If this be done the maximal and minimal pressures and oscillographic index, which fall thirty to sixty minutes after the injection of caffeine, rise again in two hours' time, and the oscillographic curve assumes a definitely hypertonic form. (4) There is no evidence of any definite relation between arterial pressure and intraspinal pressure.

## Phenolsulphonophthalein as a Test of Renal Efficiency.

292. MARION (*Le Scalpel*, August 18th, 1923, p. 909) states that Albarran's test of renal efficiency—that is, the quantity of urea eliminated in two hours after ureteral catheterization—requires a further test. A patient who is about to have a nephrectomy may excrete a considerable quantity of urea from the other kidney, and yet that kidney may be insufficient to support life, the apparently satisfactory quantity of urea excreted coming from a concentration of blood urea. These cases are rare, but nevertheless they exist. Marion cites a case of tuberculous kidney: the patient excreted 1.14 grams of urea from the apparently healthy kidney; the tuberculous kidney was removed and the patient died of uraemia; nothing to explain that renal inefficiency could be found. In another case of advanced pyonephrosis of the right kidney (due to calculus) the left kidney excreted 1.54 grams of urea in two hours; but the phenolsulphonophthalein test done at the same time yielded only 13 per cent. of that drug. A blood urea test yielded 1.21 grams of urea. The patient suffered so greatly from sepsis and fever that nephrectomy was done, but anuria gradually supervened and the patient died in eight days from uraemia. As a complementary test Marion thinks that "Ambard's constant" is too delicate and difficult for ordinary purposes, and prefers phenolsulphonophthalein, as he finds that it accords with the "constant" in almost all cases and also permits comparison between the efficiency of the two kidneys. Marion injects 6 mg. of the drug into a vein and collects the urine from each kidney every half-hour. It is unsafe to entrust the specimens to more than one observer as "colour appreciation" varies so greatly in individuals. The author gives numerous examples of the variations of the excretion of the drug in normal and pathological conditions. In a case of unilateral tuberculosis the healthy kidney eliminated 50 per cent. while the other yielded 0 per cent. In a case of renal calculus the healthy kidney excreted 46 per cent. and the diseased kidney only a trace.

have been preserved and may be further inquired into at any time. It has been our experience that once the parasites appeared they were present at all times and increased in number daily until the fever was controlled by quinine in the third week. In several of the cases the blood was taken during intertropical fever, and from a practical point of view it seems immaterial whether the blood was taken during a paroxysm or not.

E. M., male, aged 37. Admitted July 14th, 1922.  
Class I.  
History.—Patient served in the army during the war, discharged in 1918. After having been employed by a fragment of shell. He subsequently returned to work until May 9th, 1922, when he was discharged because of insanity. He was discharged from the army at that time and place, and at three years became a satisfactory account of himself. He was discharged from the army at that time and place, and at three years became a satisfactory account of himself. He was discharged from the army at that time and place, and at three years became a satisfactory account of himself.

# X-RAYS for General Practice

¶ X RAYS offer a most important addition to a General Practitioner's service, the value of which it is impossible to compute.

mean  
Accuracy of Diagnosis  
as well as  
Increased Remuneration

- ¶ There is no substitute for the X-Rays.
- ¶ A scientific and congenial service with a good remuneration
- ¶ RADIOGRAPHY BY THE NEW "Technique Director" process is now so simple that any Doctor can use it.
- ¶ Call and see the apparatus at work. Continuous daily demonstration, or send for Catalogue No. 22 B fully descriptive.

## The "General Practice" X RAY APPARATUS

is the latest production of the Medical Supply Association. Automatically safeguarding against those scientific and technical difficulties previously met by the inexperienced, it is expressly prepared for the service of the General Practitioner, and by its means he is enabled to produce valuable radiograms with ease and efficiency.

"You switch on, we do the rest."

### Price Complete:

For Alternating Current £185 0 0  
" Continuous " £230 0 0

Extra for latest modification to enable the X-Ray Tube to be used from beneath the couch upwards, as well as from above the couch downwards thereby making the apparatus universal in its application. Extra £18 10 0

NOTE.—The above price is for the complete installation, inclusive of accessories, viz:—

High Tension Transformer, Filament Heating Transformer, Filament Control Coolidge X-Ray Tube, Oak Cabinet for supporting apparatus, Radiological couch, vertical screening stand, marble switchboard, x-ray tube stand for radiotherapy and dental radiography. Foot switch for remote control, fluorescent screen with protective lead glass front, intensifying screens, intensifying screen cassette, photographic tank development outfit, dark room photographic lamp, radiographic compressor, Anti Corona high tension overhead conductors.  
PATENT FOR INVENTION FOR RADIOGRAPHY HUMAN TO USE  
THEY HAVE HAD NO PREVIOUS EXPERIENCE IN RADIOGRAPHY.

NEW MODEL.

The largest X-Ray and Electro-Medical Apparatus Showrooms in the United Kingdom.

numerous observations which I have made on the subject. Meantime, this much I know, and would here proclaim to all, that the blood is transfused at one time in larger, at another in smaller quantity; and that the circuit of the blood is accomplished now more rapidly, now more slowly, according to the temperament, age, etc., of the individual, to external and internal circumstances, to naturals and non-naturals—sleep, rest, food, exercise, affections of the mind, and the like."

But many years had to elapse before we could give a quantitative expression both to the amount of blood under normal conditions and to its variations, and explain the manner in which these variations are brought about. The Rev. Stephen Hales, second only to Harvey as an experimental physiologist, has only calculations based on measurement of the dead organ. The determination of the output in the living animal was first made in our own times, and it is only within the last ten years that methods have become available which reveal in man himself the quantity of blood leaving the heart in each unit of time, and therewith enable us to estimate the total work of this organ. If we accept the results of the former, we may say that in a normal man at rest each cavity of the heart expels about 4 litres a minute. During violent exercise, when, as we know, the requirements of the body for oxygen may be increased tenfold, this quantity rises to 24 or even to over 30 litres a minute. These figures convey only imperfectly the enormous rush of blood which is being effected by the heart under these conditions. An ordinary laboratory tap will deliver nothing like 30 litres a minute; to obtain this amount it is necessary to a course to a large tap such as that which is supplied to a bath. It means that the whole blood must pass through the heart and round the body every ten seconds and complete the circulation of the body six times in every minute. And it must be remembered that the heart is putting out this colossal amount of blood against an arterial pressure which is higher than normal and which may amount to 150 to 180 mm. Hg, as against the 100 to 110 mm. which is the ordinary systolic pressure in the arteries of a resting individual.

We see, therefore, that the heart has a marvellous power of adapting its work and its performance in accordance with the needs of the body as a whole, and is fully deserving of the feeling of respectful admiration which inspires Harvey to speak of it as "the sun of the microcosm," "the household divinity," "the foundation of life," "the source of all action."

#### ITS POWER OF ADAPTATION.

To search out the intimate character of this power of adaptation is a problem almost as enthralling as the demonstration of the circulation of blood. We find that during exercise the increased output of blood is increased to show that the increased output of blood is increased during exercise is simply an expression of the heart being so constituted that under normal conditions it will send on into the arteries all the blood that flows into it from the veins. Harvey probably had some inkling of this power when, in speaking of the action of the auricles, he ascribes to them the property of exciting a stronger contraction on the part of the ventricles, comparing the latter to the tennis player who can strike more forcibly and further if he takes the ball on the rebound.

In the intact animal a large number of processes, nervous as well as chemical, are involved in the increased action of the heart during muscular exercise. By the action of the central nervous system and of other physiological processes involved, the strain thrown on the heart is minimized, so that it can effect the increased work with the greatest possible economy of effort. But the intimate character of this power of adaptation is only fully displayed when we cut away these protective mechanisms which are normally shielding the last citadel of life, and study the reaction of this organ when it is entirely isolated from the central nervous system and is reduced to the condition of a muscular pump with valves, working rhythmically and steadily in virtue of its own automatic powers.

We can make a "heart-lung preparation" in which the lungs being retained in connexion with the heart, the blood passing through this organ is kept properly

aerated. The systemic circulation is, however, replaced by a system of elastic tubes passing to a venous reservoir, in which we can vary at will the inflow of blood into the heart, the arterial pressure (and therewith the resistance to the expulsion of blood from the left ventricle), and the temperature of the blood supplying the heart, while we can measure the pressures at any moment of time in all the cavities of the heart as well as the changes in volume of this organ. In such a preparation we find that, within very wide limits, the output of blood corresponds exactly to the inflow. Whatever is supplied to the heart on the venous side is expelled by it on the arterial side. And again, within very wide limits, whatever is the resistance to be overcome in the arteries, so long as we keep the inflow of blood constant, the output of blood by the left ventricle remains unaltered whether the pressure in the aorta be 40 or 200 mm. Hg.

We know now that the energy for all vital movements, derived immediately from the food, and in each tissue from the oxidation of the constituents of the tissue or of the blood circulating through it. It is possible in such an isolated heart to measure its respiratory exchanges and therewith the extent of the oxidative processes responsible for the energy of the heart's contraction. We then find that the amount of oxygen taken in by the heart and converted for the most part into carbonic acid is proportional to the amount of work that the heart is set to do. The isolated heart is like the whole man—the harder he works the greater are his respiratory exchanges. I am accustomed to compare the heart with an ideal motor car which, without action on the part of the driver, would automatically admit more petrol and air when the resistance to the movement of the car increases—as, for instance, in going uphill.

#### THE LAW OF THE HEART.

The heart has thus the power of automatically increasing the chemical changes and the energy evolved at each contraction in proportion to the mechanical demands made upon it, behaving in this way almost like a sentient and intelligent creature. But the cause of this power must lie in the muscular walls of the heart itself, and a study of the conditions under which it occurs and the concomitant changes in the heart has revealed the secret of its wonderful power. The solution is simple. We find that, in the isolated heart, every increased resistance to its contraction is associated with an increased diastolic volume of the cavity or cavities, which have to overcome the resistance. Putting the matter in another way, we may say that the larger the diastolic volume of a given heart, the greater is the force of the contraction which immediately ensues. The energy of contraction is therefore a function of the diastolic volume of the heart. Dilatation of this organ is not merely a pathological phenomenon, but is the means by which the heart achieves its purpose, and maintains an activity which varies with the needs of the organism for more or less blood.

In this relation we find also the secret of the power of compensation, such as occurs in cases of valvular disease and has been always a puzzle to pathologists. Injury, for instance, to an aortic valve, with the production of regurgitation, causes increased filling of the left ventricle at the following diastole, since this receives blood not only in the ordinary way from the pulmonary veins and left auricle but also by a reflux through the damaged valve. The dilatation invokes an immediate increase in the force of the contraction, so that within a few beats the left ventricle sends on into the aorta the total amount of blood flowing into it during the preceding diastole, and the aorta receives sufficient blood not only to supply the body, but to make up for the amount leaking back through the damaged valve. The same reasoning applies to the compensation which occurs for any valve lesion, increased filling or increased resistance or of a stenosis, increased filling or increased resistance and in an otherwise healthy individual constant increase in work has as a secondary result increased growth and hypertrophy of the cardiac muscle, so as to make it fit to meet the abnormally increased demands throughout life of the individual.

Acute Pericarditis per 100 rheumatic in-patients.

|         |           |
|---------|-----------|
| 1870-74 | 13.57     |
| 1875-79 | 10.96     |
| 1880-84 | 12.07     |
| 1885-89 | 9.18      |
| 1890-94 | 13.18 (2) |
| 1895-99 | 10.90     |
| 1900-04 | 9.53      |
| 1905-09 | 4.88      |
| 1910-14 | 5.09      |

(From St. Bartholomew's Hospital Reports, vols. viii-iii.)

The figures for the later years tally with those I have obtained from the St. Thomas's Hospital reports, which show about 5 per cent. of pericarditis in rheumatic in-patients. The Guy's Hospital figures (Sandison) for the decade 1900-1910 are 7.7 per cent. (St. Bartholomew's for the same period are 7.20).

I think, therefore, that there is small doubt that the incidence of acute pericarditis, the second most serious rheumatic manifestation, is falling. It would be interesting to know what is happening to the death rate from rheumatism, including rheumatic heart disease, in the country. Unfortunately the Registrar-General's returns do not permit of these figures being known with accuracy. Still we may at least say that some progress has been made, and it would seem probable that it is to clinical work rather than to public health administration that we attribute what improvement has occurred. It appears to affect the severity rather than the frequency of the disease, and this suggests that earlier diagnosis and more efficient treatment have been the factors responsible for the improvement.

Take what comfort we may from these considerations, there is not one of us here that is not profoundly dissatisfied with the rate of progress made, for rheumatism still remains one of the great serious infections of our land. What are the factors that tend to hinder us in dealing with this disease more successfully? They are numerous. We are hindered by lack of knowledge in some particulars, by lack of decision born of controversy in others, and (must I not add?) by a sensation of apathy due to familiarity with the disease. These are the matters we are to discuss to-day, and as they are so numerous, I venture to suggest that we might keep our thoughts the better in order by considering them under three headings, in each case referring to the problems of etiology and treatment:

1. The problem of the rheumatic infection.
2. The problem of heart disease in the rheumatic subject.
3. The problem of chronic cardiac insufficiency in the rheumatic heart disease.

**THE PROBLEM OF THE RHEUMATIC INFECTION.**

As I have already said, the whole question of heart disease in early life is bound up in the problem of the rheumatic infection itself. This is the fundamental matter. I start with it, and I hope in our discussion we shall not shift this, the most important question of all.

The modern view of rheumatism is that it is a special or specific bacteriæmic infection, working by repeated recrudescences and reinfections, and producing no sort of immunity against itself.

Dr. R. Duddell has kindly supplied me with the following figures from the Registrar-General's returns for the London area. They refer only to cases between the ages 5 to 15 years. They show the average annual mortality from (1) rheumatic fever, and (2) heart disease, and the mortality rate per 10,000 inhabitants. Triennial round the census years have been studied. The figures include "pericarditis" and "endocarditis," but no exclusion of non-rheumatic cases is possible.

Perhaps the only point that I need refer to in this is the claim that rheumatism is a "specific" infection by this phrase, but I mean by it here neither more than this—that the rheumatic infection produces a condition so clear-cut and differentiated that it is due (if an infection at all) to one type or strain of organisms. Bacteriologists often speak as though were no true disease "rheumatism," but we cannot do this. To see the infection at work in acute cases, during the same clinical picture again and again, I am sure of our contention. Difficulties may arise in different time to time; we may have to think of scar rheumatoid arthritis, malignant endocarditis, fibrous nodules, peliosis rheumatica (so called), the centre, as it were, there is a clear-cut entity relating itself in hundreds of cases, which is rheumatism. more than one case out of a hundred is there any and to-day we are concerned with the ninety-nine researches into the histopathology of the disease scarcely conducted by Dr. Carey Coombs, while they the bacteriæmic character of the infection, apply its specific or special nature.

I pass now to consider the main difficulties that have to be met in dealing with this disease.

**1. Rheumatic Environment.**

I do not think anything hampers us more than our lack of certain knowledge in connection with the rheumatic environment. What is the link connecting rheumatism with poverty? Is there any truth in the traditional association of rheumatism with damp houses? Shortly before the war I was able, by private means, to trace many of the cases of rheumatism in Richmond. The housing conditions were reported to me, times by amateur visitors, sometimes by the visitors ing for Dr. Duddell, the medical officer of health. was a great uniformity in the reports as to the data of the houses; many cases came from basements, where found wet walls, mildew under the eaves, even concrete foundations,\* and so forth. How these compared with others in the district I do not know, war put an end to my investigations; but when I know, as I have, of three families occupying in such the same basement, and the children of each in developing rheumatism, it makes one think that the must be of importance.

This is a public health question, and should be the appointing of some small committee of investigation. We do not need inquiry into thousands of cases, but a detailed investigation of the home circumstances of a few or so instances. Only severe cases, and preferably attacks, should be included. These could easily be through hospitals, and it might, perhaps, be best to an investigation to be undertaken in one of the provincial cities, so as to keep the cases to a small than London.

If we were sure of our facts and knew what we do to, to make rheumatism notifiable might be of service; but let us have the facts first and notifiable afterwards, later.

**2. Education of the Public.**

We are hampered in our efforts to get hold of the public, which holds that rheumatism does no in childhood. To call attention to the dangerous tre of the disease I should hesitate to suggest any great grand movement such as we have seen in connection tuberculosis, leading to such inordinate expense and remarkably poor results. By going more readily to achieve much in these directions. The parents of the

muscle to the auriculo-ventricular node, and then passes rapidly through the bundle of specialized muscular tissue, known as the A-V bundle, to all parts of both ventricles. We have in this bundle an interesting example of a muscular tissue differentiated to serve the propagation of excitation rather than for contraction, so that it closely resembles nerve in the manner of its function. To the same fine and careful experimenter we owe the explanation of one of the commonest conditions of the diseased heart—namely, auricular fibrillation or delirium, which is responsible for the irregular ventricular contractions, often leading rapidly to exhaustion and failure of the heart. It is remarkable that the clue to the explanation of this condition was first given by the observations of Romanes on the contractile tissue of jellyfish, which by its rhythmic pulsation propels these graceful animals through the seawater. It was shown by Mayer for the jellyfish and by Mines for the frog's heart that it was possible to obtain a ring of contractile tissue in which a wave of contraction passed continuously round the ring, and the merit of Lewis's observations is the proof that delirium is of the same nature as this circus movement, so that the contractile wave continually progresses over the muscular tissue, exciting each part in turn but in a completely inco-ordinate fashion. It was long ago shown by Marey that the rhythmicity of the heart was bound up with the prolonged refractory period affecting the heart muscle after its contraction, during which period it was insusceptible to any form of excitation. Lewis has shown that the same movements which are responsible for fibrillation are due to a disturbance in the normal relation between the rate of conduction of the excitatory process and the refractory period in the heart muscle. Thus instead of an orderly progression of impulses from one node to the next and so to the auriculo-ventricular bundle and ventricles, every individual fibre is contracting rhythmically but independently of what is happening in its surroundings.

#### *The Central Nervous System and the Heart.*

Time will not allow me to deal with the manner in which the heart, already so perfect as it would seem in its power of adaptation, is controlled by the central nervous system, so that the adaptation to changes in the environment and to the needs of the most distant parts of the body can be carried out with greater perfection and with the least possible drain on the energies of the heart muscle. Among such adaptations must be included those attendant on the emotions—"every affection of the mind that is attended by either pain or pleasure is the cause of an agitation whose influence extends to the heart." But indeed, Harvey's treatise, being the foundation of modern physiology, might serve as a text to a commentary, from which but little of our present-day knowledge of the organs of the body could properly be omitted.

I should like, however, to be permitted to allude to another chapter in modern physiology, which can be said to have grown out of Harvey's discovery of the circulation of the blood, and which is becoming every day of increasing importance.

#### **HORMONES.**

In the dedication to his work Harvey compares the heart to the sovereign king, and throughout he continually recurs to what we should now describe as the "integrative function" of this organ. In virtue of the circulation which it maintains, all parts of the body are bathed in a common medium from which each cell can pick up whatever it requires for its needs, while giving off in return the products of its activity. In this way each cell works for all others—the lungs supply every part with oxygen and turn out the carbon dioxide which they produce, the alimentary canal digests and absorbs for all, while the kidneys are the common means of excretion of the soluble waste products of the body. Changes in any one organ may therefore affect the nutrition and function of all other organs, which are thus all members one of another. But, in addition to enabling this community of goods, the circulation affords opportunity for a more

private intercourse between two or at any rate a limited number of distant organs.

It is now eighteen years since I drew the attention of this College to the chemical messengers or hormones which are employed by the body for this purpose. As an illustration of the method by which they work, I adduced the example of carbonic acid gas, which is the product of all cellular activity and at the same time has a specific excitatory effect on the respiratory centre, so that the respiratory movements keep pace with the needs of the whole body for oxygen. The typical hormone, however, is a drug-like body of definite chemical composition, which in a few cases is actually known, so that the substance has been synthesized outside the body. It is more or less diffusible and may even withstand without alteration the temperature of boiling water. It is generally easily oxidizable in a neutral or alkaline medium, so that after its production it does not remain long in the blood; it delivers its message and is then destroyed. Each specific hormone is manufactured by a group of cells and turned into the blood, in which it travels to all parts of the body, but excites definite reactions in one or a limited number of distant organs. The production and action of these substances are continually going on in the normal animal. They are necessary to health and their production in excess or in deficit give rise to disease and maybe to death. Typical of these substances is secretin, a substance produced in the epithelial cells lining the upper part of the small intestine when these come in contact with weak acid, so that it is produced in normal circumstances by the passage of the acid chyme from the stomach into the duodenum. Directly it is produced it is absorbed into the blood and travels round to the pancreas, to the liver, and to the intestinal glands, in all of which it excites secretion. By means of this chemical reflex the arrival of the products of gastric digestion in the small intestine evokes within a couple of minutes the secretion of the three juices whose co-operation is necessary for completing the work of digestion and solution of the food already begun in the stomach. It is probable that this mechanism is but one of a whole chain of chemical reflexes responsible for the orderly progression of the various stages in the digestion of food.

These hormones may apparently be formed by any kind of tissue. In many cases a gland which has, in the evolutionary history of the race, poured its secretion by a duct into the alimentary canal or on to the exterior, loses its duct and becomes a ductless gland, the secretion being now transferred either immediately or through the lymphatics into the blood stream. In either case these chemical messengers may be formed from masses of cells which have at no time had a glandular structure and may be modified nervous tissue, germinal tissue, or some part of the mesoblast.

#### *The Thyroid.*

As a type of the ductless gland derived from one with an external secretion the most familiar example is the thyroid. The physiological action of its internal secretion and the morbid results of its excess or deficiency, affecting tissue growth and development, metabolism and mentality, are familiar to all. In recent years the active substance has been actually isolated, and its constitution determined, by Kendal, who has shown that it is an iodine derivative of an amino-acid, tryptophane. It seems almost a fairy tale that such widespread results, affecting every aspect of a man's life, should be conditioned by the presence or absence in the body of infinitesimal quantities of a substance which by its formula does not seem to stand out from the thousands of other substances with which organic chemistry has made us familiar.

#### *The Sexual Hormones.*

But although we do not yet know their constitution, the chemical messengers associated with the reproductive organs are possibly even more marvellous in the influence they exert on the different parts and functions of the body. The effects of castration have been the subject of observation almost from the beginnings of civilization, but it is only during the

regurgitation or pericardial adhesions, but of which the most characteristic feature is the greatly diminished power of recovery in the heart muscle.

How do such cases arise? The first and most obvious thought is that they are our failures—the infection has been so severe that the first question for dissection: Is it infection or mechanical strain that has done the harm? I believe it is infection rather than exertion every time. Lack of rest may predispose to further cardiac by mechanical strain alone; always there is re-infection, therefore we must look upon these cases of chronic heart crippling as the result of repeated infections. Herein lies the importance of the problem I have already emphasized—the source of these recurrences and reinfections. In the face of such difficulties what can be done in the way of preventing and treating chronic cardiac insufficiency?

#### 1. Salicylate Therapy.—Once the heart is hopelessly damaged and the patient in a condition of chronic rheumatic toxæmia the action of salicylate is, as I have already said, disappointing. Nevertheless I believe it to be true that the more freely and persistently we use salicylate in the earlier rheumatic attacks, the less often shall we be faced with these dreadful failures. My own practice in these chronic toxic cases is to continue small doses (50 grains daily) in the hope of preventing fresh activity on the part of the infection, and to give double that dose for a few days at a time if the temperature appears to be mounting. I am aware that it is said that to persist in the use of the drug is to render it ineffectual, but when I recall all the antisyphilitic views that have been expressed in the past, I do not feel called upon to regard this statement as necessarily true. For my own part I believe that, although the persistent use of salicylate helps but little in getting rid of the last symptoms of rheumatic activity, yet it does help to prevent recurrences of that activity. I feel the responsibility of omitting salicylate is far greater than that of overdosing it.

#### 2. Cardiac Drugs.—Drugs of the digitalis group play but a small part in connexion with the heart diseases of young people. In the presence of active rheumatic carditis they are of no avail; in its absence they are seldom indicated. Occasionally they may be beneficial, used on the same lines as in the heart disease of older people. *S. viridans* from America I cannot think that this line of treatment is very hopeful. It has been extensively tried in this country, and even at the time when racine therapy was so much more fashionable than it now is, the reports were conflicting and mainly disappointing. The reasons are not far to seek. The chronic cases, such as we are now considering, are for the most part far too toxic and too ill to react to inoculation treatment. But even used as a prophylactic, is it likely to be of value? I think not, for if we know anything about the rheumatic infecting organisms it is that it fails to produce in the human subject any immunity against itself.

#### 3. Tonsillectomy.—In the earlier attacks of rheumatism with carditis I believe tonsillectomy to be the correct treatment where the tonsils are obviously diseased, and I do not hesitate if the condition of the heart permits, to recommend operation where the temperature refuses to settle down. I have never had cause to regret such a decision, although on theoretical grounds it would seem possibly dangerous; on the contrary, the results are often extremely gratifying, the temperature showing a quick return to the normal. In later cases, where the toxicity is extreme and persistent, there is seldom a chance of removing the tonsils owing to the condition of the heart. I have already said that tonsillectomy at this late stage is extremely and persistent, there is seldom a chance of removing the tonsils owing to the condition of the heart.

#### 4. Tonsillotomy.—In the earlier attacks of rheumatism with carditis I believe tonsillectomy to be the correct treatment where the tonsils are obviously diseased, and I do not hesitate if the condition of the heart permits, to recommend operation where the temperature refuses to settle down. I have never had cause to regret such a decision, although on theoretical grounds it would seem possibly dangerous; on the contrary, the results are often extremely gratifying, the temperature showing a quick return to the normal. In later cases, where the toxicity is extreme and persistent, there is seldom a chance of removing the tonsils owing to the condition of the heart. I have already said that tonsillectomy at this late stage is extremely and persistent, there is seldom a chance of removing the tonsils owing to the condition of the heart.

#### 5. Tonsillotomy.—In the earlier attacks of rheumatism with carditis I believe tonsillectomy to be the correct treatment where the tonsils are obviously diseased, and I do not hesitate if the condition of the heart permits, to recommend operation where the temperature refuses to settle down. I have never had cause to regret such a decision, although on theoretical grounds it would seem possibly dangerous; on the contrary, the results are often extremely gratifying, the temperature showing a quick return to the normal. In later cases, where the toxicity is extreme and persistent, there is seldom a chance of removing the tonsils owing to the condition of the heart. I have already said that tonsillectomy at this late stage is extremely and persistent, there is seldom a chance of removing the tonsils owing to the condition of the heart.

blood will give us assistance in getting rid of mouldy rheumatic infection. I cannot say, as I have had no experience of it in this condition, I think it might be worth a trial, as I feel it might turn the scale in patients' favour.

#### 6. Regime.—At the present time the best that is available for these cardiac cripples is prolonged treatment under a regime partly that of a hospital and partly convalescent home. There are some here to-day who have given much time and thought to this subject, and I shall not do more than try to sketch the principles of the treatment and to enumerate the various alternatives before us.

The one great object which we have in view is to prevent fresh rheumatic activity. In the absence of this I will gradually right itself as far as the previous day will permit. As regards rest, I think most necessary that prolonged and strict rest is not only necessary but advisable. The essentials of this treatment would therefore seem to be: (a) prolonged rest rather than strict rest; (b) correct hygiene; (c) close observation and opportunities for strict treatment necessary; (d) some facilities for education. The possible ways by which such treatment can be carried out for long periods are not very many:

#### Hospital.—The pressure on hospital beds renders an impossible scheme even were it practicable on grounds.

#### Ordinary Convalescent Homes.—Even were these to take heart cases we could not recommend for this purpose homes as at present run. The ordinary convalescent home in the country or at the seaside is too happy to live a place for the chronic heart case. I think physicians have quite given up sending such cases to convalescent homes even where they will be accepted. Many children's hospitals manage their own convalescent homes and manage to do well. The children are admitted full instructions for treatment, they are visited by who have seen them when at their worst, and the hospital is ever ready to readmit the case should need arise. The length of the patient's stay sometimes depends on the management of the home, but on the whole this is a satisfactory arrangement except for the educational facilities.

#### Special Heart Homes.—In many ways special hospitals constitute the ideal way of treating these cases, I am glad to say that at last some such homes have opened and more are in the process of being planned. Such homes should be within touch of the hospitals, I fear that there is no doubt that every large city should not be insuperable. The chief disadvantages of providing special homes for heart cases seem to be that they must always be costly to run; other cases are admitted, and the long delay before supply of such homes can be adequate. It has taken more than ten years, to my personal knowledge, to get the best now available; and I am not without hope that we shall be able to prevent these cases more quickly than we are able to provide for them at the present rate of progress. *Special Beds in Convalescent Homes and Country Houses.*—I think much might be done, and without delay, by the setting aside of special beds in the existing convalescent homes and country hospitals. It has suggested that chronic heart cases might well be taken in conjunction with surgical cases of tuberculosis. In groups there is the same need for prolonged treatment as in the case of tuberculosis. In the case of education a certain amount of education would be

## THE WISDOM OF THE BODY.

If iodine be entirely absent from the drinking water and the soil, so that it is not contained even in minute quantities in the vegetable food grown in the district, the thyroid undergoes hyperplasia—in a vain endeavour to make bricks without straw, to produce its proper hormone without iodine. This seems to be the cause of the great prevalence of simple goitre in certain districts—especially in Switzerland and in parts of the United States. It has been shown that goitre can be practically eliminated from these districts by the occasional administration of small doses of iodine or iodides (Marine, Lenhart, Kimball and Rogoff). These results were communicated in 1917 to Dr. Klinger of Zürich, and as a result of his experience the Swiss Goitre Commission has recommended the adoption of this method of goitre prevention as a public health measure throughout the entire State. Already great progress has been made in the abolition of this disease from the country. Thus the incidence of goitre among all the school children of the canton of St. Gallen has been reduced from 87.6 per cent. in January, 1919, to 13.1 per cent. in January, 1922.

## II.

Where a disordered condition is due to diminished production of some specific hormone we may extract the hormone from the corresponding gland or tissue in animals. It is characteristic of these hormones that, so far as we know, they are identical throughout all the classes of vertebrates, it is possible that they may be found far back in the vertebrate world. This method is easy when, as in the case of the thyroid, the active principle is stored up in the gland and is unaltered by the processes of digestion, so that we can obtain all the curative effects of the hormone if we administer dried thyroid by the mouth. We have no evidence that any other of the hormones with which we are acquainted partake of this resistance to digestion, so that to produce their specific effects they have to be introduced by subcutaneous injection—a great drawback when the administration has to provide for the constant presence of a small concentration of the hormone in the blood and tissues. In the case of insulin, for instance, it seems necessary to repeat the injection every twelve hours to obtain any continuity of action, and the same thing probably applies to the pituitary extract, while in the case of the genital hormones no reliable effect has been obtained except by the actual implantation of the organ from an animal of the same family.\* We may, however, look forward to the day when the chemical constitution of all these hormones will be known, and when it may be possible to synthesize them in any desired quantity. We may then be able to overcome the inconvenience of subcutaneous injection by giving relatively colossal doses by the mouth, or we may be able to modify their constitution to a slight extent so as to render them immune to the action of digesting fluids without affecting their specific action on the functions of the body.

## III.

The ideal, but not, I venture to assert, the unattainable, method will be to control, by promotion or suppression, the growth of the cells themselves whose function it is to form these specific hormones. Though this method seems at present far from realization the first steps in this direction have already been taken. It must be remembered that

\* In my Croonian Lectures in 1905 I reported some experiments made in conjunction with Dr. Lane-Claydon, in which I had produced hypertrophy of the mammary glands in virgin rabbits, and in some cases actual milk production, by the daily subcutaneous injection of the filtered watery extract of young rabbit foetuses. Similar results were obtained by Fox. But a weak point in these experiments was that the ovaries had not been previously extirpated. Aneel and Bouin have shown that in the rabbit the mere rupture and discharge of a Graafian follicle, with the subsequent growth of a corpus luteum, are sufficient to cause hypertrophy of the mammary glands (the effective hormone presumably having its seat of manufacture in the luteal cells). It seems possible, therefore, that the effect of our injections may have been on the ovaries, and that the growth of the mammary glands was only a secondary and indirect result. I do not therefore now regard our experiments as conclusive.

the power of controlling growth of cells involves the solution of the problem of cancer. Here the experiments on the growth of normal cells outside the body have shown that they can be stimulated to vie with cancer cells in the rate of their growth, or can be inhibited altogether according to the nature of the chemical substances with which they are supplied. And we know that the growth of certain cells, such as those of the mammary gland or of the uterus, is excited by specific chemical substances produced in the ovary or foetus; and we may be able to find specific substances or conditions for any tissue of the body which may excite growth which is retarded, or diminish growth in the ovary in excess. It may be that in some cases purely mechanical interference will suffice. Thus in experiments by Steinach and others it has been found that ligature of the deferens close to the testis, while causing atrophy of the seminiferous cells, brings about overgrowth of the interstitial cells, which, as we have seen, are chiefly responsible for the hormones determining the secondary sexual characters. Among these secondary sexual characters must be classed the whole of a man's energies. Virility does not mean simply the power of propagation, but connotes the whole part played by a man in his work within the community. As a result of this actual rejuvenation in man, and thus to have warded off for a time senility with its mental and corporeal manifestations. Further experiments and a longer period of observation are necessary before we can accept these results without reserve, but it must be owned that they are perfectly reasonable and follow, as a logical sequence, many years' observations and experiments in this field.

It would indeed be an advantage if we could postpone the slowly increasing incapacity which affects us all after a certain age has been passed. Pleasant as it would be to ourselves, it would be still more valuable to an old community such as ours, where the arrival of men in places of rule and responsibility coincides as a rule with the epoch at which their powers are beginning to diminish. The ideal condition would be one in which the senile changes affected all parts of the body simultaneously, so that the individual died apparently in the height of his powers. For it must not be thought that in any such way we could prolong life indefinitely. Pearl has pointed out that if all the ordinary causes of premature death were eliminated, this would increase the average duration of life by not more than thirteen years. On the other hand, he shows that the children of long-lived parents have an expectation of life which is twenty years greater than that of the average individual.

It is evident, then, that if longevity is our goal it is not medical science we must look to but eugenics, and I doubt whether the question is one with which we are concerned. The sorrow of life is not the eternal sleep that comes to everyone at the end of his allotted span of years, when man rests from his labours. It is the pain, mental and physical, associated with sickness and disability, or the cutting off of a man by disease in the prime of life, when he should have had many years of work before him. To us falls the task of alleviating and preventing this sorrow. In our childhood most of us learnt that suffering and death came into the world through sin. Now, when as physicians we stand on the other side of good and evil, we know that the sin for which man is continuously paying the penalty is not necessarily failure to comply with some one or other of the rough tribal adjustments to the environment, which we call morality, but is always and in every case ignorance or disregard of the immutable working of the forces of Nature which is being continually revealed to us by scientific investigation. In spite of which I have drawn your attention, suffering is still widespread amongst us. Only by following out the injunction of our great predecessor—to search out and study the secrets of Nature by way of experiment—can we hope to attain to a comprehension of "the wisdom of the body and of the understanding of the heart," and thereby to the mastery of disease and pain which will enable us to relieve the burden of mankind.

[illegible]

ultimately between life and death, amounted quantitatively to one part in twenty-five hundred of the total food eaten. We now know that if a particular fraction of the oil had been given, instead of the intact oil, the amount might have been much less than this.

Such facts, abundantly confirmed as they are, surely imply that the dogmatic teaching of twenty years ago must be profoundly modified; they have indeed no inherent lack of probability which would justifiably stand in the way of their frank acceptance. We are familiar in quite other connexions with the potent influence which infinitesimal quantities of specific material may exert in biological phenomena. In the region of nutrition itself we have been learning that even micro-organisms with highly developed synthetic powers may require in their environment substances which specifically stimulate growth, and this especially when they are adjusted to parasitic habits and therefore to complex media. The animal is essentially parasitic upon the green plant, and there is no reason why its needs should be confined to the substances which the plant makes in large amount. It is sure from the work of recent years that if we wish criteria for an adequate diet we must not confine our consideration to pounds and ounces, nor, for that matter, to calories. This is a scientific certainty; whether it has practical importance is a matter for separate consideration.

I have so far spoken almost as though I were putting before you a new and unfamiliar subject. My only justification for doing so is that I feel these general observations provide a background for the presentation of some general details. I can in reality, of course, assume a general familiarity with the facts. I must do so, indeed, in the short time at my disposal I am to attempt a personal estimate of the present outlook. All I can do, indeed, is to report upon certain facts established by the most recent researches which seem to make firmer the basis for a belief in the objective reality of these accessory nutrients, and to illustrate the practical importance of their study.

I can assume your acquaintance with the fact that at least three distinct substances are known to exist which conform to the only available definition of a vitamin. Each possesses, that is to say, a nutritive importance which is very great, while its actual concentration in natural foodstuffs is very small. Perhaps, for convenience of reference, I may just enumerate them, familiar though they be. They are: (1) vitamin A, originally known as the fat-soluble vitamin; (2) vitamin B, the antineuritic substance; and (3) vitamin C, the antiscorbutic factor. That we should speak of them in this non-committal way, with merely alphabetical labels, was a suggestion due to McCollum, which at present seems well justified. It is well, too, that we should adopt Drummond's suggestion and write "vitamin" instead of "vitamine," as by doing so we avoid certain unjustifiable chemical connotations in the name. In my second lecture it will become clear that the vitamins A, B, and C probably do not stand alone in their class.

It is clear that if the distribution, properties, and functions of substances are to be established, quantitative methods for their estimation are a *primo* necessity. It is no less clear that to find such methods in the case of substances which have not been isolated, and cannot therefore be weighed, is no easy task. Nevertheless, owing to pioneer efforts made years ago at the Lister Institute, and to the later work of many—in particular that of Osborn and Mendel, of Drummond and Zilva, and of Mottram—it may be honestly claimed that we have now a technique of sufficient accuracy in the quantitative sense for the establishment of many definite conclusions. This technique is based upon biological experimentation. It consists essentially in determining the minimal amount (or the relative amount in comparison with a standard preparation) of the material under study which will induce certain observable effects in a standard animal—the smallest amount proved in-stance, which, when added to a dietary previously proved not to maintain growth, will enable this normal growth to occur in a young animal; or the amount which will prevent or remove symptoms experimentally produced in an

animal by deprivation of the particular vitamin in question. I must not stop to discuss the details of technique. All cautious observers have found that such methods call for experience, and call for standardization, but all agree that reliable results are to be obtained. The number of such observers is becoming legion. Experiments which began in this country and were immediately prosecuted with great enterprise in the United States are now being carried out in almost every civilized country.

The application of the above methods is continuously increasing our knowledge of the exact distribution of vitamins. This assuredly, if we are to believe at all in their significance, is a subject of much practical importance, but one upon which I need not dwell.

We are learning much that is interesting concerning the origin of vitamins. Although the statement may ultimately have to be qualified, it may be said generally that it is to the plant cell we must look as the essential place of origin. Vitamins arise in the green plant as the result of photosynthesis, though in the case of A at least, to judge from the work of Coward and Drummond, as part of events which are independent of the chlorophyll function. The relatively great stores of A which accumulate in the livers of fish take origin from the diatoms and algae of the sea (Hjort; Coward and Drummond).

Concerning the general chemical and physical properties of vitamins there is one statement to be made which is of considerable practical importance. There long existed a very general belief that these substances as a class were easily destroyed by heat, and upon this was based the popular assumption that any form of cooking necessarily reduces the vitamin content of natural foods. It must not be supposed that this belief is wholly wrong, but it requires considerable modification. Three years ago I was able to establish the fact that the vitamin A is resistant to heat though very prone to destruction by oxidation. Since then various observers, in particular Hess and Zilva, have shown that the same is true of vitamin C. Zilva has further determined very carefully the conditions which make for stability in the case of the latter (the antiscorbutic) substance. He found, for instance, that de-citrated lemon juice when left slightly acid (pH 6.8) could be boiled for two hours in an atmosphere of carbon dioxide without loss of antiscorbutic potency. By boiling, however, for only one hour in a current of air the potency was greatly reduced. The process of oxidation, which in the latter case was mainly responsible for the destruction, occurs much more slowly if the fluid be rendered more acid. At pH 2.2, for instance, oxidation is found to be quite slow. In the alkaline condition vitamin C is much less stable, though in this case also it is oxidation rather than the effect of heat which determines its rapid destruction (Harden, Zilva). The vitamin B has long been known to be resistant to heat.

It follows from the facts just enumerated that if access of oxygen be avoided foodstuffs may be heated to boiling point with relatively little danger from the standpoint of vitamin destruction. It should be remembered, however, that ordinary cooking operations in no case wholly exclude oxidation.

Considerable progress is being made in our knowledge of other chemical and physical properties of the individual vitamins. This knowledge, together with a realization of the conditions which make for their stability, is notably assisting current attempts to isolate the substances. Although in no case has final success been reached, preparations of each vitamin have been obtained possessed of such potency as to indicate that they contain the active substance in a concentration enormously in excess of that in the original source.

In the case of vitamin A, for instance, several observers have been able so to fractionate cod-liver oil as to obtain a product of which much less than a milligram could serve as an efficient daily ration for a rat. Of the B vitamin Seidall has made a preparation capable of preventing polyneuritis in pigeons when administered in doses of at most 1 milligram. In spite of the high activity of such preparations the final endeavour to separate from them an active pure substance has so far proved in all

upon other structures which are more susceptible to its action than the neurones. But we know that the end-result of a reflex, or any other form of nervous activity, is manifested in various degrees of strength, so that there must be some method of graduating the response of the effector organ. The individual nerve impulse is invariable, but the number and frequency of the nerve impulses in the neurone may vary within certain limits, as can also the number of neurones set into activity. The latter factor is probably the most important one in bringing about the graded response.

It is only seldom that the full activity of any organ or tissue of the body is required, and in some of them there is evidence that the active units are constantly varying. The phenomenon of fluctuation or variable activity can be demonstrated in the capillaries where changes are constantly occurring in the amount of circulation going on in any one capillary field. It is probable, though not certain, that the same phenomenon takes place in the nervous system. In the production of a minimal response in any effector only a few neurones suffice to carry the nerve impulses necessary, and it is likely that the ones actually employed are continually varying, there being active phases and resting phases for each individual neurone or groups of neurones. Such distribution of function is possible where there is a large reserve of units, and provides the body with a system which is capable of nicely graduated response to the widely different conditions it has to meet, and at the same time avoids the occurrence of fatigue in those parts of the nerve pathway, the synapses and receptive substances, which are susceptible to its incidence.

The first analysis of stimuli takes place in the receptors, which are so fashioned that normally they respond only to certain forms of energy. Light is the only stimulus which is normally capable of exciting the receptors of the retina, and is ineffective elsewhere. Similarly heat, cold, tactile impressions, and other stimuli, can only excite nerve impulses if they meet with receptors which they are capable of stimulating. If suitable receptors are not present in a tissue the stimulus is incapable of exciting nerve impulses unless it is so gross as to be a direct excitant of the neurone itself. The tissue is therefore incapable of sensation and of reflex response to such stimuli. On the other hand, forms of energy which can excite the receptors present set up nerve impulses which are carried by afferent neurones into the central nervous system. The individual nerve impulse is the same, no matter what its origin may be, so that its end-result must be finally determined by the nature of the response of the organ to which it is carried. In its passage through the central nervous system the nerve impulse has a number of potential pathways opened up to it by the branching of the neurones over which it travels, and is therefore capable of following various routes and so giving rise to a variety of end-results. The pathways are not, however, equally open. The synapses between the neurones interpose different degrees of resistance to the passage of the nerve impulse. The synapses, therefore, are structures which regulate the number of neurones engaged. The factors which alter their resistance will be discussed at a later stage.

If the nerve impulse is to give rise to sensation it must be carried to some part of the higher level of the central nervous system which is associated with the reception and interpretation of that particular form of sensation. If it is to bring about a reflex it must be conveyed by efferent neurones to some effector organ. The separation of the impulses giving rise to sensation and reflexes can take place at various levels in the nervous system.

While the end-results of the nerve impulse in any neurone is mainly determined by the anatomical connexions of that neurone, it is also dependent upon the nature of the amount of competitive substance the nerve impulse meets with material under stimulus of the neurone. The final efferent neurones effects in a standard way carry nerve impulses which excite in substance, which, when they inhibit the activity of the muscle according to maintain growth of substance between the neurone and to occur in a young animal substance of Langley, or prevent or remove symptoms exhibited—is of an excitatory or case of voluntary muscle the

final efferent neurone ends only in excitatory material in the muscle, and the nerve impulses conducted to it always produce contraction of the muscle.

Voluntary muscle, however, is capable of being inhibited just as involuntary muscle is, and the process by which this is effected is similar in character though different in the site of its operation. In the case of voluntary muscle inhibition is exercised upon neurones in the lower level of the central nervous system, and the actual site appears to be in the synapse which intervenes between the last efferent neurone and the one immediately before it. Instead of the muscle being directly acted upon the inhibition is exercised upon the efferent neurone which supplies the muscle; in other words, the inhibitory substance is not in the muscle but in a synapse in the lower level of the central nervous system.

#### THE SYNAPSE.

We do not know the nature of the process which goes on in the synapse or even its exact anatomical structure, but many facts have been ascertained about the results it produces, and all point to its extreme importance. The synapse is irreciprocal and only allows the nerve impulse to pass through it in a forward direction. It does not conduct the nerve impulse as rapidly as does the neurone, and the passage of the impulse is always delayed there. The synapse interposes resistance, and a resistance which is capable of great variations in degree. A single stimulus of an afferent nerve sets up a nerve impulse which may fail to pass the synapse or synapses interposed on a reflex arc, even in a spinal animal, and it is only by repetition that the synapse becomes penetrable. The resistance of the synapse can be altered by a variety of circumstances. The repeated passage of a nerve impulse over it results in a lessened resistance, and the impulse then passes more readily. Repetition facilitates the passage of the nerve impulse over the synapses in any chain of neurones, and the effects may be more than temporary, so that one gets what is sometimes spoken of as "canalization." This implies that a path has become so "grooved" or deeply worn by frequent use that nerve impulses entering it tend to run in the same channels and produce the same end-results. As far as we know, such grooving of paths in the central nervous system is one, not of the neurones, but of the synapses which lie between them. The lowering of resistance occasioned by repetition of the nerve impulses through the synapses is of great importance. It is part of the normal process of education, and habits and skilled movements are thus acquired. Bad habits and abnormal ones may also be established by repetition, and the more frequently the nerve impulses pass through the same synapses the more difficult it becomes to re-educate the synapses, and to direct the nerve impulses into other pathways. This is true not only of the synapses on the pathways of nerve impulses bringing about reflexes, but also of those which carry nerve impulses giving rise to some forms of sensation. Conditions of hyperaesthesia and of hyperalgesia may be due to several causes. The receptors may undergo changes in adaptation and become more sensitive to stimulation, or the synapses may become less resistant in some part of the afferent paths, thus allowing the nerve impulses to pass more readily to the cerebral cortex. In conditions in which there is an increased irritability of the central nervous system the increased reaction appears to be due to a lessening of resistance in certain synapses; the response of the neurones is not altered in amount or in character but is more easily elicited.

The synapses may undergo alterations which modify not only their resistance but may completely change the nature of the influence the nerve impulse is capable of exerting upon the following neurone. Just as the receptive substance of muscle may be excitatory or inhibitory so the synapse may be excitatory or inhibitory. The synapse, however, differs from the receptive substance in that it can apparently alternate between the two phases and be excitatory or inhibitory as required. The inhibitory action exerted by the synapse appears to be more than a mere block to the passage of a nerve impulse, because it may prevent the neurone which it inhibits from being set into activity by other neurones. The nature of the alteration

agreed that the chance of prevention depended upon the future might happily bring suffering, and it left open what other prophylactic measures the future might happily bring.

Dr. A. P. Thomson (Birmingham) reviewed his personal experience in dealing with the problem at the Baskerville Institution in Birmingham. The outstanding clinical difficulties were two: (1) To determine when the infection giving rise to carditis had become quiescent. (2) To discover when the child had become free of relatively free from the danger of reinfection. He described the methods that he had made to obtain an answer to these questions, but stated that simple reliable tests of general application had not yet evolved. Dr. Thomson stressed the importance of education in dealing with these children and claimed that one solution lay in proper use of the defective Children Act, but he agreed fully with the view that the patients should not lose touch with the medical schools.

Moffett advised their own doctor at home or a free dispensary nurse to see that treatment was carried out continuously until convalescence was given. Much longer periods of rest were required. The organization of a very successful Cripples' Union had been formed to form a similar society for the care of rheumatic cripples. The municipal Cripple School was taking a few cases. It was, however, a small number as compared with the total. The education of these children presented difficulties. They were backward from delinquency prolonged absence from school. When they returned they were worried by their low position in school and tried to catch up, with the result that they often broke down again. They should be taught separately in smaller classes on modified Dalton plan. Expense, however, barred the way at present. Dr. Moffett had a suspicion that the gap between the curriculum of the infant school and that of the upper school was too wide, and in the attempt to bridge it chorionic membrane cases were very resistant to advice and persuasion. Many heart cases were very resistant to advice and persuasion. When examining for the Women's Volunteer Reserve early in the war, Dr. Moffett found a surprising number of congenital heart cases among a set of young women of magnificent physique and very capable. Many were leading very strenuous lives with no symptoms and no knowledge of their cardiac trouble. It seemed cruel to enlighten them. Sir Thomas Horder (London) referred to the etiologic difference which existed between mitral regurgitation and mitral stenosis. Although both of these forms of valvular damage were undoubtedly due to the operation of rheumatic virus, mitral regurgitation was in most instances the residual effect of an acute rheumatic infection, whereas mitral stenosis was generally a progressive sclerosing and fibrosing process resulting from subacute or chronic rheumatism. He quite agreed with Dr. Hawthorne (then said that, even though they might be ignorant of the causative agent in acute rheumatism, they were able to recognize the disease process within very narrow limits. However, that a much greater difficulty presents itself in the case of subacute and of chronic rheumatism associated with carditis; in them there was room for the consideration of non-specificity in relation to the various causes met with.

Dr. G. J. Luskater (Manchester) said that it was perhaps well to remember that the recognition of subacute rheumatic phenomena in children might be exceedingly difficult, especially in the busy out-patient department of a general hospital, and the frequency of unexpected cardiac lesion would indicate how frequently these cases were missed. Further, the investigation of rheumatism was included in the pathology of the streptococcus; the work of Royston in America and Dible in England showed too clearly that great difficulties involved when dealing with this group of organisms, and so progress was doubtless delayed. Reference had frequently been made in the meeting to the parallelisms between tuberculous and rheumatic infection and Dr. Langley wished to carry this a step further. The work of Marston Patterson had fully shown how a beneficial auto-inoculation might be both produced and controlled in graduated exercises in tuberculousis, the temperature giving a faithful record of the response as soon as it was to be returned to the patient or to the inoculum. At present the response of the rheumatic patient to such auto-inoculation was only recognized in the form of a recurrence of the disease, and was not in the form of a temperature rise as was the case in tuberculousis.

subjective or objective, should be carefully recorded and analysed. Many of them appear to be common to a number of different conditions, but it is hoped that they will eventually be capable of classification, and thus provide the material for an early diagnosis of the conditions producing them.

## THE TREATMENT OF GENERAL PARALYSIS BY INFECTION WITH MALARIA.

BY

W. McALISTER, M.A., M.B., Ch.B.,

DEPUTY PHYSICIAN SUPERINTENDENT, ROYAL HOSPITAL AT MORNINGSIDe.

This paper is intended to give a preliminary account of an experiment in the treatment of general paralysis of the insane which has now been in progress for several months in the Royal Hospital at Morningside under the supervision of Professor George M. Robertson. Despite the fact that the etiology and the pathology of the disease—at least in their more significant details—have been successfully worked out, treatment has lagged far behind. Indeed, for the time being an impasse has been reached in the approach to the problem along the accustomed lines, and resort is being had to more empirical modes of treatment. Not that these are to be despised—if their fruits justify them, few will be found to cavil at their use.

In this latter category of reputed remedies one must place the treatment of general paralysis by inoculation with the plasmodium of malaria. The method has been used for a few years by Wagner von Jauregg in Vienna and by Weygandt in Hamburg, with results which, if confirmed, can hardly fail to arrest attention. It is claimed, for example, that out of a large number of patients treated in the course of twelve months no fewer than 41 per cent. can be regarded as completely cured; 20 per cent. sufficiently recovered to be able to resume their occupation though still retaining minor disabilities; and 10 per cent. as improved but not sufficiently so to warrant their discharge. The remainder failed to respond adequately to the treatment. The difference in the response to treatment seems to vary with the length of time the disease has been in progress before inoculation with malaria is resorted to. Thus, among the "cures" the duration was never more than two and a half years; among the "improved" the period was three and a half years; while in the case of the others the disease was of old standing. In practically every case, however, some improvement followed the treatment. In the most successful cases the physical signs of the disorder are said to have disappeared completely, though the laboratory findings—for example, the Wassermann reaction in the blood and cerebro-spinal fluid and the cell count and globulin content of the latter—remained unchanged. On the mental side there is reported a corresponding improvement. In other cases, though the results have been less satisfactory, there has apparently been some alleviation of the severity of the symptoms and a retardation of the rate of deterioration so characteristic of the disease. Such claims, confirmed as they were by the testimony of visitors to Wagner von Jauregg's clinic, seemed eminently worthy of practical investigation, and so the experiment was set in train.

### Mode of Inoculation.

The first difficulty encountered at Morningside, when the experiment was resolved upon, was to procure a suitable supply of the virus. The help of the local health authorities was enlisted, but an exhaustive inquiry elicited the surprising fact that there was not at that time within the Edinburgh area an uncomplicated case of benign tertian malaria. The London School of Tropical Medicine was then approached, but even had a supply of the organism been available from that source, the practical difficulty of transporting it alive to Edinburgh was deemed insuperable. Just then there was admitted to Craig House from Burmah a young man whose mental breakdown was attributed to recurrent severe attacks of malaria, though no accurate information as to the type could be gathered. In due course this patient had a bout of fever which on clinical grounds

appeared to be benign tertian malaria, and this was confirmed in the laboratory. As an additional precaution Colonel Marshall, Lecturer in Tropical Diseases in the University of Edinburgh, was called in consultation and confirmed the laboratory findings. But for this fortunate coincidence the initiation of the experiment might have been indefinitely postponed.

On March 29th of this year the patient referred to had a paroxysm, at the height of which venipuncture was performed and sufficient blood withdrawn in an ordinary syringe to inoculate twelve cases of general paralysis. Each of these received a subcutaneous injection of approximately 2 c.cm. of infected blood. The site of the injection was the loose skin just below the angle of the scapula. When the needle was inserted the subcutaneous tissues were probed in all directions to a distance of about  $1\frac{1}{2}$  inches so as to diffuse the plasmodium and promote absorption as rapidly as possible. A simple dressing of sterile gauze was affixed to the puncture by means of collodion, and any swelling resulting from the injection gently massaged. The patients immediately resumed their normal mode of life, but careful records were kept of their temperatures.

On reflection it would appear more prudent, in view of the difficulty of obtaining supplies of the virus, to substitute individual inoculation for the mass inoculation practised in this instance. In this way the virus can be kept alive for a long period of time by the inoculation of one patient from another in series. The one drawback would be that results would take longer to accumulate.

### Incubation Period.

In every case the infection "took," though there were considerable variations in the length of the incubation period. The earliest cases had their first definite attack after eight days; a group followed the next day, and the others were spread out at irregular intervals till the sixteenth day. One case did not react till twenty-eight days had elapsed; while in another the interval was thirty-two days. Whenever a case was reported as having developed malaria a microscopic examination of the blood was made to confirm the diagnosis.

### Subsequent Treatment.

The infection was allowed to run its course unimpeded for any number of paroxysms up to twelve—the average number being ten. During this time sponging was resorted to when required, but nothing more was done so long as the patient tolerated the condition well. In only two cases was it considered advisable to kill off the infection before the regulation number of paroxysms had occurred. In one of these an intercurrent affection occurred two days after the inoculation (and in no way dependent on it) and ended fatally, while in the other the decrepit condition of the patient before inoculation held out little hope that he would successfully carry the additional burden of a series of severe malarial attacks. He was therefore allowed to have only three paroxysms. To arrest the infection quinine hydrochloride was given in doses of 10 grains four-hourly for three days, and thereafter 5 grains thrice daily for fourteen days. In every case the temperature began to subside immediately after the administration of quinine was commenced, and by the fourth day was as a rule stabilized. In none of the cases has there been to date any recurrence of the malady.

The manifestations of malaria were in no way modified by its occurrence in cases already suffering from general paralysis, except that its discomfort was as a rule borne with forbearance which was as praiseworthy as it was unusual. On the fourth day after the subsidence of the temperature an intravenous injection of 0.3 gram novarsenobillon was given. This was repeated at weekly intervals for six weeks. There was generally a well marked degree of secondary anaemia after the infection had run its course, treatment for which was given simultaneously with the antispasmodic remedy.

Following is a brief account of the twelve cases treated:

#### CASE 1.

An advanced case of general paralysis lasting for two and a half years. The patient died of peritonitis three days after inoculation.

As we well know, several very important causes of paralysis are on the recurrent laryngeal nerves, many causes of paralysis of one or both vocal cords. The most common are aneurisms, enlarged ganglia, and malignant disease of the mediastinum, the oesophagus, or the thyroid. I have notes of 11 cases of paralysis in which it was caused by pulmonary tuberculosis, and in many of these cases, before the nerve is attacked, attacks of glottic spasm, by irritation, attacks of glottic spasm, but these may occur after paralysis has been established, in other words, these and similar lesions may cause spasms, or paralysis, or both.

GOUT, RHEUMATIC, CARDIC, OR PYLOMAYR CASES

No inconsiderable number of cases of spasms of the glottis have come under my observation which were functional, which never developed into any serious local trouble, but which were seldom noticed until they occurred in elderly persons, and were most common at night. The patient, as a rule, goes comfortably to sleep but awakens with an irritation or tickling in his throat; soon this becomes so violent that he awakes and the spasms continue until he is relieved by help or until he falls off bed to some article of furniture while he passes through the stages described under "Phenomena of glottic spasms."

Similar attacks, in stout and elderly men with empty stomachs, may occur in the morning, while dressing. Slight dysphagia—like brushing the teeth—may arise from them, and with retching or vomiting but no relief comes with the expulsion of much mucus from the trachea. They are less severe and alarming than when due to the

The cardiac cases are more numerous: they appear to be more frequent in emphysematous subjects; the attacks may be among the earliest symptoms of disease of the heart, aorta, or mediastinum. The gouty or rheumatic cases are more difficult to distinguish and may only be postulated by a process of exclusion.

In that rare affection, true pachydermia laryngis, there may be spells of coughs with glottic spasms. I have watched some cases for years. But I am not certain that the pachydermia is the cause, for I have seen the disease persist while the cough and spasms entirely disappeared.

I am not at all sure whether there are any large forms of pertussis occurring in adults. I well know colleagues who in the past have been called upon to come along at once and do up a child or two with "whooping cough," but I have never seen any such cases.

My first impression of the man was that he was a very intelligent, well-educated, and very capable man. He was a very good person, and I was very much impressed by his personality. He was a very good person, and I was very much impressed by his personality. He was a very good person, and I was very much impressed by his personality.

possibly performed treacherously for which he was quite prepared. His face was dusky and sagged, his skin clammy with exhaustion and fear, and his pulse was bounding. His arms were perfectly free, there was no stenosis anywhere, striking evidence of the stress and strain of the glottic spasm he had endured—the pulse and flaves were irregularly spindled with purple patches of ecchymosis. These were the consequences and not the cause of his choking spells. The severity of the latter was further shown by small petechiae on his face and body and by a ruptured right intercostal membrane (ribs) and

The fatal cases are generally attributed to asphyxia. But have often noted that most cases of death following an asphyxial stenosis (whether cerebral or pulmonary) are accompanied by a certain amount of cyanosis, and this, in turn, is not without pathological significance, as it is part of the general picture of asphyxia.

[illegible]

under my care, before he was released. It was lucky for him

every sign that the malady was gaining the mastery. He appeared to be quite demented, and physically he was but a pitiable shadow of his former robust self. To-day he is to all outward appearance in excellent physical health. His habits are tidy; his speech movements, which were formerly almost wholly disorganized, are now well co-ordinated; and his vitality is not now drained by bouts of severe seizures as it previously was. Admitting, as one must do, that it is difficult owing to his taciturnity to assess the degree of mental enfeeblement which remains, yet one cannot but be struck by the general transformation. The other case is described above as No. iv. Here the conspicuous change is in the patient's mental state, though his physical health is also improved. To those who knew him in his former phase he now appears a new creature, a different personality altogether. In the remaining cases lesser, though often substantial, changes are common, but it is now generally recognized that many of these changes (for example, in the character of the pupillary reaction) may develop in the ordinary course of the disease. The average duration of the disease in the twelve cases was two years, and in every case the greatest care in the diagnosis was taken, all the usual serological tests being applied. At the moment these are again being investigated and so far as this has been done Wagner von Jauregg's conclusion that the condition of the blood serum and cerebro-spinal fluid is not materially altered by the malarial infection has been confirmed.

To the extent, at least, that none of the patients are any the worse for their experience, the experiment has been justified. Time alone will show whether any further justification will be forthcoming. Assuming that the results eventually turn out to be more favourable than they seem at the moment, how is the phenomenon to be explained? As long ago as 1883 Clouston described two cases in which mental disorders had been arrested by incidental sepsis, originating in one instance in the parotid gland and in the other in the hand. This led him to prophesy that "some day we shall hit upon a mode of producing a local inflammation or manageable septic blood poisoning, by which we shall cut short and cure attacks of mania"—the type of disorder from which his two patients suffered. The hypothesis underlying Wagner von Jauregg's work is virtually identical with that which Clouston here adumbrates, though it is applied to a very different form of mental disorder. Their common quest is for an infection which, while not of itself endangering the patient's life, will either stimulate the common bodily defences against the original disease or else will facilitate the operation of remedial agents. With this end in view some experimental work has been done with tuberculin and vaccines of different strains of staphylococcus. Apart from the risks involved in the use of these, the results from a therapeutic point of view have not been encouraging. Later still, attempts have been made to produce a more active bodily defence along some particular line without evoking the risks and discomfort of a general febrile disturbance. In this connexion some work has recently been done in Morningside with substances—for example, phlogestan—which produce a leucocytosis without the other accompaniments of fever. Here again, though a definite leucocytosis could be maintained for a prolonged period, the results of such treatment in cases of general paralysis were negligible. Whether the method of treatment with malaria will prove more efficacious time and a large field of experiment will be necessary to show. And even if the claims made for the treatment are in the long run substantiated there will remain to be answered many questions: Is the high temperature which can be produced incompatible with the well-being of the spirochaete? Has the infection with malaria any influence on the permeability to salvarsan of the choroid plexus? If the success of the method does not depend on such more or less mechanical effects, what subtle chemical changes occur? That these cannot be answered at the moment is enough to invest the further progress of the experiment with engrossing interest.

#### Conclusions.

1. Of the nine cases in whom the treatment was completed two are conspicuously improved; in one case the

emphasis is on the mental, in the other on the physical improvement.

2. Besides these, four other cases show some improvement, although not so marked.

3. In the remaining three cases no distinct change occurred. It is noteworthy, however, that in none of cases has there been any progressive deterioration. This is specially true of the only early case—No. vii.

## THE TREATMENT OF GENERAL PARALYSIS BY MALARIA.

BY

A. R. GRANT, M.B., CH.B. ABERD.,  
DEPUTY MEDICAL SUPERINTENDENT, COUNTY MENTAL HOSPITAL,  
WHITTINGHAM.

WAGNER VON JAUREGG's<sup>1</sup> malaria treatment of general paresis, and the excellent results published by him Gertsman,<sup>2</sup> Weygandt,<sup>3</sup> Kirschbaum, Delgado,<sup>4</sup> and of first attracted our attention in the early months of 1922 and through the kindness of Professor Stephens of Liverpool School of Tropical Medicine, who inoculated first cases for us, we were able to commence this treatment in July, 1922.

Mosquitos are common at Whittingham, and recognizing the possibility of spreading malaria we had, prior to commencing treatment, examined many mosquitos at within a mile of the hospital building, and felt that only varieties of *Culex* were present. In September of this year, however (fourteen months later), a full hunt for mosquitos revealed the presence of *Anopheles plumbeus*.

Whilst recognizing the impossibility of the restoration of degenerated cells and fibres we hoped for destruction of spirochaetes and complete and permanent arrest of degeneration. Authorities explain the influence of malaria upon the course of general paralysis in different ways. It is the destructive influence of high temperature as such spirochaetes, as shown by Jahnke and Weichbrocht;<sup>5</sup> it is conceivable that waves of high temperature, as in malaria, may be more efficacious than continuous temperatures. Muehlens and Kirschbaum<sup>6</sup> believe that following inoculation there is a marked impoverishment of the blood, followed by a rapid regeneration of blood, which leads to a non-specific reactivation of the immunity processes. This theory would be supported by the views of Hauptmann. If these theories be correct, then the temperature and impoverishment of the blood should be aimed at.

It seems possible that different strains of *Plasmodium vivax* give different clinical types of malaria. Authorities recognize only three species of malarial parasites, while others count double this number; it appears that Muehlens and Kirschbaum were using a strain of *P. vivax* giving a different clinical type of malaria from ours, for in their experience of 76 cases of artificial malaria jaundice occurred in 12 cases, while in our 40 only one case of jaundice has been observed.

It was with these considerations before us that, in inoculating cases with quartan, malignant tertian, and two strains of benign tertian, we decided to allow the first two to die out except the second strain of benign tertian, which we named "W." This strain from the first gave a reasonably high temperature and a moderate degree of anaemia. It has produced no untoward effects, no local disturbance at the seat of injection, and no marked enlargement of the spleen. All cases have once responded to quinine, and there have so far been no relapses. This strain has already passed through many hosts and is at present in use in other hospitals. It seems advisable to name the strain so that it may be traced, for many points, such as increase or weakness of the virulence of the parasite, and various other questions which arise, will be more easily answered when the strain has passed through many more hosts than at present.

action of the anæsthetic on the medulla. I have over and over again pointed out the presence and persistence of this stenosis during my operations of laryngotomy. The larynx is, in that operation, split open and absolutely shut off from any connection with the trachea and lungs; the anæsthetic (administered through the tracheotomy opening) does not come in contact with the laryngeal mucosa, which is rendered insensitive with cocaine; and no mucus descends from the pharynx to irritate it. Yet the cords (or the one cord, when the other has been removed) remain in the cadaveric position, within whose orb it continues to make its limited to-and-fro excursions. Is this position due to spasm or paralysis? Is, doubtless, the best known manifestation of "laryngeal spasm," but is it a spasm and due to overcontraction of the glottis-closing muscles, or may it be due to loss of abductor tonus or even paralysis of the posterior muscles? Certainly a very comprehensive and modern medical dictionary defines laryngismus stridulus as "a disease of children marked by sudden laryngeal spasm, with a crowing inspiration and the development of cyanosis." I studied writing the chapter on the subject in my textbook, and then came to the conclusion that the phenomena were not caused by a spasm of the glottis-closing muscles, but by a paresis of the opening muscles; that it occurred more in the baby and feeble than in the hyper-sensitive and readily responsive; and that, therefore, treatment by stimulation, tonics, and improved nutrition was not only indicated but was, in practice, more successful than soothing treatment by sedatives, anaesthetics, and so forth. It is certainly not due to a peripheral nerve lesion. There is no endolaryngeal cause, and the name, "laryngitis stridulosa," is a misnomer. It is curious that it should be more common in male children. But as we have the opportunity to-day of hearing the views of those who must see a good many more cases than the laryngologist, I should be very glad to hear their opinion on these points.

*Is larynx a "Glottic Spasm"?*—A sudden, complete, and involuntary closure of the glottis, announced by the well known sound, certainly takes place. But is the affection not a good illustration of my thesis that many cases of what are readily accepted as spasmodic contraction of certain muscles are really due to the paresis of their opponents? Surely the sudden, powerful, and irregular contraction of the diaphragm, innervated by the phrenics, is the most important feature; and this sudden unexpected descent takes the glottis, so to speak, unawares when its abdomen tonus is impaired by neurosis (as in asthmatic attacks), or when the respiratory centre is depressed by alcoholic intoxication, by uræmia, or after surgery, is in the diaphragm, the vocal cords, no longer at the correct "concert-pitch," by the abdominal tonus, are suddenly sucked together, and the characteristic click of a hiccup due to a parietic and not a spasmodic laryngeal action.

*Chronic Spasm of the Larynx.*—Time does not permit of my referring to the interesting cases of rhythmic attacks—clonic spasm or hysterismus—affecting the cords or arytenoids, and generally associated with similar spasms in the pharynx and fauces. They are said to occur in paralysis agitans, after meningitis, in epilepsy of the brain, bellum, and in disease of the medulla in the neighbourhood of the accessory nucleus.

As regards treatment I can be brief. It depends on the diagnosis and the etiological factors. It will vary according to our decision that the symptoms are produced by the accessory nucleus.

*TREATMENT.*  
As regards treatment I can be brief. It depends on the diagnosis and the etiological factors. It will vary according to our decision that the symptoms are produced by the accessory nucleus.

reversive effect of strong smelling-salts, cold affusion, and ordered to keep the mouth closed and to breathe quietly through the nose. A few puffs into the pharynx of a weak solution of cocaine (2½ per cent.) will check a large number of cases. It is not wise to put this remedy in the hands of patients with functional spasm. Between the attacks the exciting cause must receive appropriate treatment. In all cases any source of irritation, such as dust, alcohol, tobacco, indigestion, or excitement, should be avoided. In functional cases the undue sensitiveness may be allayed by bromides and a sedative regimen. But the important thing is to treat the patient's general condition by regulating the diet, hygiene, and habits, and eliminating all possible causes. In some individuals cases I have traced the spasm to the morphine or cocaine habit. The treatment of spasm of central origin is purely symptomatic, as the primary disease is usually incurable. In tabetic crises, bromides, iodides, chloral, antipyrin, and morphia may be required, and I have had to advise in cases of recurrent paralysis associated with attacks of spasm. But I have never had to perform it during an attack. I do not have I ever met with a case of functional spasm where it was necessary.

SM JAMES DUNN-GRAVE, K.B.E., M.D., F.R.C.S.

Consulting Surgeon, Central London Throat and Ear Hospital.

After the interesting and stimulating review of the subject presented by Sir Sclat Thomson, I propose to confine myself to a few personal observations and views. Such spasmodic conditions of the glottis may be due to hyper-excitability of the cortical centres for adduction of the cords (the phonatory centres), or to overaction of the centres in the bulb of which the adductor centres appear to be the stronger. The former is probably the main element in the glottic spasm of children (laryngismus stridulus), the latter in adults.

Laryngismus stridulus must be distinguished from laryngitis stridulosa, the usual condition spoken of as a group. My experience confirms the statement that the former occurs almost exclusively in the subjects of ticks. In this disease there is a deficiency of calcium in the blood. Calcium is known to act as a sedative to the nervous system, and its absence leads to a relative hyper-excitability, with the natural consequence—an abnormally vigorous reaction to any irritation, either local or distant among the former may be cited the irritation produced by the increased pharyngeal secretion accompanying adenoid in the nasopharynx. A singular instance of a distal source of irritation is illustrated by the case of a young male infant brought to me in view of the possibility of laryngeal obstruction. The little patient had attacks of stridor wild violent excitement, followed suddenly by a state of exanthematic. This suggested the infantile masturbation described most graphically in Bruns's work on *Kindheitskrankheiten*. Inquiry elicited from the father the observation that during the attack there was a condition of priapism, and on inspection there was found an excessive tightness of the prepuce. Circumcision was advised, and it was followed by complete recovery.

I have observed the occurrence of laryngeal spasm in women at the menopause. A very suggestive instance of laryngeal spasm of sexual origin is quoted by Moritz Schmidt as narrated by Boeck. It occurred in the person of an important widow and her second husband.

He was inoculated with benign tertian on September 8th, 1922. During the attack of malaria and for some weeks afterwards his mental condition underwent a change. From being apathetic and lacrymose he developed well marked auditory and visual hallucinations, and also delusions of persecution, which for a time made him very troublesome with his food. Gertsman refers to similar cases and seeks to explain the presence of the auditory hallucinations by the greater infiltration of the temporal lobes. The patient, however, made a good recovery and was discharged. He has since written a letter to his medical officer which shows that he has at present remarkably good insight.

On his discharge (June 30th, 1923) the following notes were made: *Nervous System*.—Pupils: right, slightly irregular, reactions (direct and consensual) to light sluggish; left, dilated, oval reactions to light, direct sluggish, consensual absent. All superficial reflexes equal and present; tongue, no tremors; speech, no impediment. Right knee-jerk diminished; left knee-jerk diminished; sensations normal, gait normal; Rombergism absent. Plantar flexor; sphincters normal. In good bodily condition. Cerebro-spinal fluid: Lange gold test, zone 2 curve; gamboge, precipitation in all five tubes; cell count 61; Wassermann test positive. Blood: Wassermann test positive 1 in 5.

## CASE II.

J. A., male, aged 36. Admitted October 11th, 1922. History.—Patient is unmarried. He is stated to have had ordinary health prior to being wounded in the head during the late war. He was, however, in the army until September, 1919, and was able to follow his employment until July, 1922, when he complained of severe headaches. No history of his having contracted syphilis has been given. On admission he was rambling and incoherent in conversation, disorientated, wet and dirty in habits. He usually lay in bed with his legs drawn up, and his face partially or wholly covered with blankets. He was in poor bodily health; unable to walk; his weight was 9 st. 4 lb.

On examination, the cardio-vascular and respiratory systems were normal. The pupils were small, unequal, irregular, and sluggish; tongue and lips tremulous; speech slurring; knee-jerks positive; plantar flexor; showed intention tremors in hands. The blood cerebro-spinal fluid both gave a positive Wassermann reaction; Lange gold test, zone 1 curve; gamboge test, precipitation in all five tubes; protein tests, positive; cell count 24.

He was inoculated with benign tertian on January 25th. At the end of March he was noted to have improved a little mentally—he was not so apathetic; there was also a slight improvement in his physical condition and he was just able to walk. In another month his condition improved both mentally and physically; he still remained wet and dirty in habits, but was able to walk a great deal better. By the end of June he was no longer wet and dirty in habits. His weight had increased by 2 st. and he was able to walk fairly well. At the time of writing he is in good bodily health, is able to walk fairly well, takes an interest in his surroundings, but his memory is very defective for recent and remote events.

## CASE III.

J. W. B., male, aged 52. This patient contracted syphilis in 1906; he was diagnosed as a case of general paralysis in 1915 in another mental hospital, and was discharged presumably in a state of remission. He was admitted here in December, 1921. From the date of his admission until May, 1922, the disease did not seem to be making much progress so it was decided not to inoculate him with malaria. In the beginning of May, 1923, however, he had several seizures and his condition began to deteriorate rapidly. He became wet and dirty in habits, and eventually a bedsores developed. It was then decided to inoculate him with malaria. This was done on June 9th, and on June 20th he was put on quinine. Since that date he has improved steadily. He is up and able to walk about, the bedsores are practically healed, and his mental condition has improved a great deal.

## CASE IV.

J. B., male, aged 54. On admission the patient was simple and childish; was completely disorientated for time and place. He was in feeble physical condition. Since March of this year he had been confined to bed and he was unable to do anything for himself. Tremors of his hands and was unable to walk about. He still has tremors of the right hand, but is able to work in the ward. His mental condition is much better; he is now orientated for time and place. The rapid amelioration of his mental and physical condition was commented on by his relatives.

## CASE V.

R. B., male, aged 44. This patient made a spontaneous recovery from his attack of malaria. Parasites appeared in his blood nine days after inoculation; they remained in the blood for thirty-nine days, and then disappeared. He has had no rise of temperature since, nor have any parasites been found in his blood. A period of over three months has now elapsed.

Of the 40 cases under treatment during the past fourteen months, 6 have died. Three patients have been discharged to their homes and are now following their usual occupations. Three patients formerly wet and dirty in habits have ceased to be so. Two of the cases formerly confined to bed have regained their strength to a considerable degree and are able to be up and about.

We are of opinion that this form of treatment is worthy of an extended trial, as, in our experience, benefit seems to be obtained in almost every case. In 236 cases Gertsman

claims to have obtained a complete remission in 38 per cent. So far, we are not in a position to make a similar claim. Our idea in this article has been to record preliminary observations on the 40 cases under treatment in the hope that we may be able to refer to them at a later date.

It has been suggested that better results might be got from subjecting the patient to relapsing fever, a spirochaetal infection which produces a continuous fever for three or four days instead of an intermittent fever for a longer period. It is hoped that the antibodies produced will have an effect on the *Spirochaeta pallida*. We have, again, through the kindness of Professors Stephens and Yorke, been able to inoculate with relapsing fever, and we hope to be able to refer to this form of treatment again.

## THE CARE OF CHOREIC CHILDREN.

BY

A. DINGWALL FORDYCE, M.D., F.R.C.P. EDIN.,  
HONORARY PHYSICIAN, ROYAL LIVERPOOL CHILDREN'S HOSPITAL.

The overflowing nervous energy of healthy children exhibits itself in lively motor activity, which to the adult eye appears constant, and may be regarded as uncontrollable. The healthy child is nervous in the sense that his nervous system is comparatively unstable; but, granted moderate heredity and suitable hygiene and environment, he develops within the bounds of an ever-increasing power of control. Psycho-analysis and neurology must here be based on child-study and experience of children; knowledge of the characteristics of childhood is the essential basis for the interpretation of nervous phenomena. Much can be learned by close observation of emotional control, mental activity, and the neuro-muscular condition, but it is important not to exaggerate the significance of nervous symptoms. A marked form of this spasm in some form is a common symptom in most illnesses. Its form of expression ranges from general restlessness to twitching of individual muscles, from violent convulsion to faint tremor.

## DIAGNOSIS.

The "nervous" child oversteps the limit of self-control. The mild initial symptoms of "nervousness" are excessive motor and mental activity. Later, it may be noticed that, while the mental activity remains excessive, it becomes increasingly associated with emotionalism, and a lack of sustained or reserve motor power. The child is easily tired, he is irritable, he cries readily, and jumps at sudden sounds, etc. There may be motor lethargy, unwillingness and inability to play strenuous games. With further development of the condition emotionalism becomes more strongly marked, lack of reserve mental power and even mental peculiarity supervenes, and motor spasms occur. The cause of such a "nervous" condition is usually complex. Neurotic heredity is common, and, when present, is usually supplemented by neurotic environment. An extreme sense of responsibility on the part of the parents or guardians, or their ignorance or fear, often develops the unsuitable environment.

Frequently, however, the nervous element, whether in heredity or environment, is not primarily at fault. The common basal error in these cases is digestive. Irregular, improper, or excessive diet deranges digestion, and manifold sequelae result—among them nervous instability, diminution in the power of control, spasm. Endocrine function is sometimes, but rarely, markedly affected.

This "nervous" child is, further, exposed to the common hazards of childhood. In outstanding degree he is liable to suffer shock from the onset of puberty, from arresting and violent psychological stimuli, and from rheumatic infection;

GENERAL DISCUSSION.

Dr. Peter Macdonald (York) stated that he had had a special opportunity of observing this condition, as a near relative had a partial thyroidectomy performed, leading to damage of the nerves of the glottis. She had had several attacks of laryngeal spasm each year, during sleep as a rule. One vocal cord was paralyzed. A manoeuvre which seemed to help was a knee-elbow position, with depression of the mandible, an endeavour being made at the same time to phonate the sound "aa."

The President said that the general practitioner saw these cases, not the consultant. Tracheotomy might actually be called for. He mentioned a case in which introduction of an endoscope gave rise to spasm of the larynx and diaphragm. He quoted Sir Felix Semons' advice to the patient to hold his breath while twenty was counted and then to take short rapid nasal breaths.

Dr. William Hill (London) quoted two cases, one a syphilitic who died in hospital without operation, while the other died, as laryngotomy was being performed, from heart failure.

Mr. A. J. Wright (Bristol) spoke on the occurrence of laryngeal spasm in whooping-cough in adults, and quoted a case which occurred in an old lady.

Dr. Day McKenzie (London) said the cause of the condition had to be diagnosed in a few seconds. He agreed that the laryngeal tonsil was a common origin for the reflex.

Hæmorrhoids :

MEDICAL, SURGICAL, OBSTETRICAL.

ANTE-PARTUM HÆMORRHAGE DUE TO PLACENTA PRÆVIA, ASSOCIATED WITH ALBUMINURIA AND ECLAMPSIA.

The following case of placenta prævia associated with albuminuria, which is the second I have had, is perhaps worth recording, because when ante-partum hæmorrhage is associated with albuminuria it is usual to regard the hæmorrhage as of the accidental type. When, however, two cases like this occur in the practice of one medical man within two years, it seems probable that the association of placenta prævia and albuminuria is not uncommon, and that the usual inference that ante-partum hæmorrhage with albuminuria means that the bleeding is of the accidental type is not always a safe one to make. The point has an important bearing on treatment because, although this particular case recovered under expectant methods, the mother would have been spared a recurrence of hæmorrhage and probably would have recovered more rapidly from the albuminuria if labour had been induced, as is usual in cases of placenta prævia.

A married woman, aged 35, had two children: the first died in infancy, and the second when six weeks old developed smothering. The history revealed that her last menstrual period was in September, 1922, but the definite date in that month could not be obtained. Examination per vaginam showed the cervical canal quite closed and, with the exception that a clot was found in the vagina and was not disturbed, the examination was negative. She was placed in the supine position and left since bleeding had stopped, with instructions to send immediately should it recur. The history revealed that her last menstrual period was in September, 1922, but the definite date in that month could not be obtained. Examination per vaginam showed the cervical canal quite closed and, with the exception that a clot was found in the vagina and was not disturbed, the examination was negative. She was placed in the supine position and left since bleeding had stopped, with instructions to send immediately should it recur.

Mr. Sowerthill Hastings (London) said that it was rarely fatal, medical men were apt to feel that about laryngeal spasm. He recorded a case in which motor ataxy being present, he performed tracheotomy saved the patient.

Mr. E. D. D. Davis (London) quoted a case of the larynx following passage of an antral cannula.

Mr. Mark Howell (London) referred to Mackenzie's account of spasm; gastro-intestinal derangement, he said, were a large factor, which was most common among children of the poor. It led to enlargement of the lingual tonsil, which was the most prominent cause of glottic spasm.

Dr. Davison (Queensland) quoted a case following operation for tonsils and adenoids, which was cured after a successful tracheotomy.

Sir Stirling Thomson, in reply, said that he was often in tabetic cases. In regard to Mr. Mark Howell's remarks, he always read Morell Mackenzie, and he always read Mackenzie's account of spasm; gastro-intestinal derangement, he said, were a large factor, which was most common among children of the poor. It led to enlargement of the lingual tonsil, which was the most prominent cause of glottic spasm.

Dr. Davison (Queensland) quoted a case following operation for tonsils and adenoids, which was cured after a successful tracheotomy.

Certain points stand out prominently in the records. Chorea commonly recurs; it is not uncommon to meet with cases of recurrent chorea in which there is no other evidence of rheumatism and no cardiac lesion; but with recurrent chorea the heart is usually involved. In connexion with tuberculous infection the following points were noted: habit-spasm is common in the cases of children suffering from tuberculous lesions; chorea sometimes occurs after acute localized tuberculous infection or an operation for the same, and in such a case, so far as here noted, is non-rheumatic; tuberculous infection sometimes supervenes after true Sydenham's chorea with cardiac involvement.

But the most outstanding feature in the records is as regards home conditions. Many of these children relapse frequently, become weakly invalids, have little education, and find it hard if not impossible later to obtain any work for which they are fitted. On the other hand, those children, even when crippled by heart affection, who survive childhood with a modicum of education, with fair vitality, and who are able to work and find work suited to them, are those whose home conditions, though poor and often to the outside eye dismal, are described as good of their class.

Apart from actual lack of the necessities of life and maternal overwork, lack of wisdom in the home is the common determining factor in the welfare of the child. Members of the Child Welfare Association do a great work in attempting to remedy this—a work ultimately of lasting educative value, and which deals with the problem at its root. But the day is yet far distant when the possibilities and wisdom in our poorer homes will prove a satisfactory or thoroughly responsive medium for even the wisest of health visitors. For the wisest of our well-to-do the problem is very difficult, and particularly so at the time of puberty and with the vista of life's work in view.

Our children's hospitals receive in their wards children till the age of puberty, and with the development of country hospitals such as Heswall suitable and picked cases may reach this age with possibilities otherwise unattainable of a useful active life. But at this most critical period adequate support suddenly fails. True, if the patient be sufficiently ill he will be admitted to a general hospital, or perhaps a convalescent home; but even there he is not graduating for a useful life. If he is merely weakly, there are large numbers of dispensaries or out-patient departments which he can attend, while living at home, and such medical supervision may suffice to give him a satisfactory introduction to adult life.

But many of the cases of the type of which I speak are of an intermediate group, for whom the latter routine is insufficient, and who, if subjected to it, inevitably sink in the physical scale, and for whom the prospect of life is unutterably dreary—if life itself is retained. For these, then, who need, and who are capable of usefully responding to, special environmental opportunity at this critical period, what possibility presents itself? Just as in the case of tuberculous infection medical care is incomplete without restoration to safe life in the sanatorium and colony, so in these cases medical effort is frustrated without supervision and direction during the years of puberty and adolescence. The "Trade School for Cardiacs" in America deals with such "occupational" or "follow-up" therapy. The children with whom we have dealt here are potential or early "cardiacs," and, from the commonest of their neuro-muscular symptoms, education made a spontaneous recovery. Parositis appeared in his blood nine months with, and then disappeared. He has had no rise of temperature since, nor have any parasites been found in his blood. A period of over three months has now elapsed.

Of the 40 cases under treatment during the past fourteen months, 6 have died. Three patients have been discharged to their homes and are now following their usual occupations. Three patients formerly wet and dirty in habits have ceased to be so. Two of the cases formerly confined to bed have regained their strength to a considerable degree and are able to be up and about.

We are of opinion that this form of treatment is worthy of an extended trial, as, in our experience, benefit seems to be obtained in almost every case. In 296 cases Gertsmann

### PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, 1923.

#### SECTION OF MEDICINE.

Sir THOMAS J. HORDER, Bt., M.D., F.R.C.P., President.

#### DISCUSSION ON THE ETIOLOGY AND TREATMENT OF HEART DISEASE IN EARLY LIFE;

WITH SPECIAL REFERENCE TO THE PREVENTION OF  
CHRONIC CARDIAC INSUFFICIENCY.

#### OPENING PAPER

BY

REGINALD MILLER, M.D., F.R.C.P.,

Senior Physician to Out-patients, St. Mary's Hospital, and  
Physician to Paddington Green Children's Hospital, London.

THE honour of opening this discussion, of which I am very sensible, carries with it no small obligation, for there is no doubt that our subject—that of heart disease in early life—constitutes one of the major problems concerning the nation's health.

Directly we begin to think of this subject as a national question we find ourselves thinking in terms of one disease and one disease only, that of acute rheumatism—that great, essentially British, infective disease. Other diseases there are which will affect the hearts of children, and, of course, they are not ruled out of our discussion; but for practical purposes the problem of heart disease in early life is commensurate with the problem of rheumatic infection. It is to this subject that I shall confine my remarks, and for the purpose of our discussion I have somewhat painfully dissected out and labelled some of the various difficulties which keep us back from a more successful control of the disease.

#### PROGRESS MADE.

Before passing to these difficulties I think it might be of interest to express a personal opinion upon the progress made in the fight against this disease. The chief change in the last fifty years seems to be a reduction in the frequency of the severer manifestations of the disease. Taking all types, mild and severe alike, I suppose the frequency has declined a little; this is merely an impression, but the following considerations seem to prove the gradual reduction in the number of the severer types.

(a) *Hyperpyrexia*.—In 1882, to judge by the fifteenth volume of the *Transactions of the Clinical Society*, physicians would seem to have met with twenty, thirty, or even more cases in their own experience.\* I doubt if anyone here has seen half a dozen. At Guy's Hospital, in the ten years 1900-1910 there was one case in 1,053 instances of "rheumatic fever." At St. Mary's Hospital in the last fifteen years I can recall two instances. The most dread of all rheumatic symptoms seems to be disappearing.

(b) *Rheumatic Admissions*.—The number of cases of severe rheumatism severe enough to require admission to hospital is also declining. Taking quinquennial periods from 1869 to 1914, the St. Bartholomew's Hospital reports show that the number of rheumatic cases per 100 medical in-patients has dropped from roughly 10 to 5. Instead of common cases, something over 200 cases a year, there are now improper, or exceeding over 100.

sequence result—*pericarditis*.—The proportion of rheumatic in-patients suffering from acute pericarditis perhaps gives sometimes, but not an accurate idea of what is happening. This "nervous" shows the percentage worked out in quinquennial periods (post-war figures are not yet available):

ears 1873-77 at the Middlesex Hospital out of 778 cases of were 53 instances of hyperpyrexia (loc. cit., p. 263).

Professor Raymond Pearl discusses at length the statistics concerning the influence of alcohol consumption on the dura-

On the other hand, the author's argument is not entirely convincing. He argues that the relationship between the consumption of alcohol and the duration of life is not as simple as it seems. He points out that the relationship is not linear, and that the duration of life is not simply a function of the amount of alcohol consumed. He also points out that the relationship is not the same for all people, and that the duration of life is not simply a function of the amount of alcohol consumed. He argues that the relationship is more complex than it appears, and that the duration of life is not simply a function of the amount of alcohol consumed. He argues that the relationship is more complex than it appears, and that the duration of life is not simply a function of the amount of alcohol consumed.

These are the action of alcohol on man, is, of course, a subject which those who desire to avoid controversy leave alone; presumably controversy has no special terrors for the authors of this volume, and they will probably enjoy the storm which it appears to be raising. Unfortunately controversy and in consequence public attention will probably concentrate on the least important passages in the book, for Professor Stenling has a neat turn of phrase and a pleasant sense of humour. We have already seen one review which considered its attack on the statement that tetraol dinners

The chapter which deals with the influence of alcohol on the community certainly invites controversy, for in this connection many social and economic factors have to be considered in the pharmacological action of alcohol, and these the author treats with the same authority as he does not claim to speak with in physiology. Professor Starling's general conclusion is that alcohol is a pleasant thing, that it is often a useful thing, and that there is no reason to abolish it because it is abused by certain members of the

We are not prepared to agree with the author in all cases with regard to the relative emphasis he has laid on the various points that have to be considered in judging the action of alcohol on the community. Our chief criticism is that he hardly lays sufficient stress on the fact that alcohol is a habit-forming drug. Regarding this he writes:

"Every action which is sufficiently temperate to become a habit, and which is not so excessive as to become craving for alcohol, is, an overreaching desire to take another dose as soon as the effects of the last begin to pass off. But this craving or habit is not as marked as in the case of other drugs" (p. 151).

[illegible]

control, and that alcohol does a service to the community by hastening their elimination. This view cannot be considered to be finally proved, and it seems much safer to assume that a normal individual risks the formation of an alcohol habit if he regularly exceeds a certain very moderate amount of alcohol for any prolonged period.

As regards the economic aspects of the problem, Professor

Starling says: "In a recent paper by Professor Collis it is pointed out that in

[illegible]

Naven and Mera in their book on *Kala-azar* state the peculiar local conditions which determine the frequency of accurate statistics collected by those on the spot with practitioners in the endemic areas is clear up the difficulties. The book is written in a performance of assisting practitioners in performing tasks, by indicating the means of arriving at a diagnosis and the questions to which investigation should be more especially directed. The disease is stated to be both in town and country, but chiefly in old-established rural communities. It is often found in villages surrounded by trees and decaying vegetable but not in new villages. The exact mode of infection has not as yet been discovered, but the possible means of infection, transmission of excretions or secretions, or transference by the agency of a blood-sucking insect directly to man, or through an alternative host (hairs, fleas, etc.), is a matter of direct importance. Spread of the disease from the skin through the agency of a sucking insect. There is at present no proof that any of these is the route used, but the most probable are considered to be by the peripheral blood or by the infestational track. In hospital, cases of kala-azar are usually treated in the general wards, but no case has been seen from the wards is known, although few insects are entirely free from the bed-bug. Of the blood-feeding insects the bed-bug is the most suspect, although it is by no means proved. The authors give a graphic description of the symptoms of the disease, but state that a diagnosis on clinical grounds is not justifiable. The less

only is seldom used in the laboratory methods of diagnosis, including bedside laboratory methods.

ceivable movement except "twitch"? They should learn that the early signs of chorea are exaggerated fidgetiness, inattention, stupidity, naughtiness, and emotionalism.

### 3. Bacteriological Cause.

The uncertainty which it is still the fashion to express on this matter hampers our clear conception of the disease. Has not the time arrived when we can agree that the infecting organism is an alimentary streptococcus? For my own part I regard this as well proven. I do not here intend to detail the evidence which has been brought forward by Poynton and Paine and many of their successors. In my own experience I have seen the streptococcus isolated by clinical bacteriologists who had been taught that it was impossible to find it; and I have been associated with experimental work and have noted its baffling alterations in virulence. One fact weighs enormously with me—that of obtaining the organism from the cerebro-spinal fluid in an occasional case of chorea. What can we think in such a case but that there is a causal connexion?

That the streptococcus cannot be separated from certain types of alimentary streptococci is not, to my mind, against this view; on clinical grounds nothing is more likely than that the rheumatic agent is a constant inhabitant of the alimentary tract. I feel that, after all the years that have elapsed, we might now agree that in the theory of the causation of rheumatism by an alimentary streptococcus we have a complicated key which fits a complicated lock.

### 4. Salicylate Therapy.

Our treatment of rheumatism must suffer if we cannot decide what action salicylate has upon the disease. This is another long-standing controversy: does salicylate act by diminishing the activity of the rheumatic infection? I see no escape from the conclusion that it does. To deny any bactericidal action to this drug in rheumatism is to be left without any explanation of its curative action in acute rheumatic arthritis. I suggest that the explanation of the action of salicylate in rheumatism is as follows.<sup>2</sup> In this infection we have three sets of tissue changes set up. First, we have focal interstitial inflammatory lesions, the direct result of the infecting organism. These are the chief changes seen in acute arthritis, acute tonsillitis, and in acute pericarditis where it exists without much myocardial damage. These are well controlled by salicylate, and we may say that where the patient's symptoms are due to this type of lesion the clinical result of salicylate therapy is satisfactory. But, secondly, we have toxic parenchymatous changes often affecting the "noble tissues" of the heart muscle and brain. No bactericidal drug could here do more than prevent further damage by putting an end to the infection. Therefore, where the patient's symptoms are due to such changes as these, salicylate acts at a disadvantage, although it still does some good. In this category come myocarditis and chorea. The large effusions sometimes left in joints when the pain and fever have disappeared, rheumatic anaemia, and nodules are (clinically) in a somewhat similar position. All these are results of an infection and will persist although the infective activity has ceased. Lastly, there are the changes induced by healing processes, which, of course, salicylate cannot touch.

With such an explanation as this we feel that we can use salicylate with freedom. The effective dose in children is from 60 to 120 grains a day, and in practice it is most important that the daily dose should be divided up into many small doses, rather than given in a few large ones. It must be remembered that it is the patients with much cardiac dilatation who are apt to vomit with salicylate; however carefully it may be given, about 30 per cent. of such cases tolerate it badly.<sup>3</sup>

I come now to two clinical difficulties which have a very real bearing on the prevention of chronic cardiac insufficiency, but I deal with them now as they are connected with the infection itself. I hope to receive much help from our discussion on these two questions.

### 5. Source of Recrudescences and Relapses.

The first of these concerns the origin of the renewals of activity on the part of the infection. I suppose we should

all agree that early attacks may often be traced to tonsillar infections, and I think where only early attacks are considered the removal of the tonsils may do permanent good. But it is now generally recognized that where there have been repeated attacks tonsillectomy often fails to prevent further trouble. Whence come these later attacks? Are they from the alimentary tract, the mouth, or the bowel, or do they originate from foci left encapsuled in the tissues of the body? In some cases it would seem that they are not really fresh attacks but recrudescences of an infection which has never truly been quiescent. I confess that this whole subject, important though it is, is full of mystery to me.

### 6. Test of "Cure."

Another very difficult clinical point concerns our appreciation of the time when rheumatic activity can be said to be at an end. I think it most difficult to be sure of this. Personally, I attempt to judge by three tests: first, the loss of the toxic appearance of the patient; second, gain of weight; and third, the temperature. Of the three I lay most stress on the child's appearance. The temperature chart is not an easy guide. A really "flat" chart, I think, may safely be regarded as meaning an absence of infective activity, but one showing irregularities I regard as uncertain; while any regular swinging of the temperature, whether it swings above the normal or (as so often in chorea) keeps entirely below the normal line, I regard as meaning some remaining rheumatic activity. With the greatest care, however, I find it hard to judge between an infection really quiescent and one which is smouldering on in a low state of activity.

### PROBLEM OF HEART DISEASE IN RHEUMATIC SUBJECTS.

I come now to speak of the causation and treatment of heart disease in patients who are already infected with rheumatism. Heart disease in rheumatism is largely a matter of the severity of the infection and the age of the child. It is a well recognized rule—although chorea will sometimes furnish exceptions to it—that we do not find acute rheumatism of the "adult" type (in which the heart tends to be spared though the infection be severe), under the age of 10 or 12 years. Below this age, and often above it, rheumatism is essentially an infection of the heart.

I leave for the moment cases of the type which goes on to chronic cardiac crippling, and speak here only of the commoner type, in which the heart, although showing signs of damage, seems to recover its functioning power satisfactorily. In such cases the heart has nearly always been damaged before the child comes under treatment, and, in my experience, if the heart has escaped, it will remain free from damage in most instances once the child is admitted to hospital. Therefore, so far as these cases are concerned, our principles of treatment consist chiefly of (1) early diagnosis and (2) efficient treatment for the infection.

1. *Early Diagnosis.*—I would like here to emphasize the fact that although often the severe symptoms of rheumatism develop with a rush, yet they have nearly always been preceded by mild symptoms which have been neglected or misinterpreted. It is during this stage of invasion that we want to get their child under antirheumatic treatment.

2. *Efficient Treatment.*—Our aim here must be to subdue the activity of the infection by salicylate while sparing the heart as much as possible by resting the patient. These two measures are the best preventives of cardiac rheumatism. I do not know of anything else that can be done to prevent the heart's being involved, or to put an end to carditis should it exist, with the exception of the use of counter-irritants to the precordium in cases of acute pericarditis. In the cases I am here considering these measures are usually successful.

### PROBLEM OF CARDIAC CRIPPLING IN RHEUMATIC HEART DISEASE.

The last problem I have to consider is that of the chronic heart invalid: the type of case which has great enlargement of the heart, with mitral disease and often aortic

Professor Raymond Pearl discusses at length the statistics concerning the influence of alcohol consumption on the duration of life. He shows that most of the statistics produced to prove the relation between the consumption of alcohol and the duration of life are riddled with fallacies. His conclusion is that the moderate use of alcohol produces no demonstrable effect on the mean duration of life, but that this is diminished by excessive drinking. As he points out, this is exactly the conclusion most unprejudiced observers arrive at by the exercise of common sense. As an instance of the care needed in interpreting statistics, Professor Pearl gives a curve (p. 265) which shows that the death rate in the United States for the last fifty years has varied inversely as the consumption of alcohol per head. As the author says, "This diagram is rather striking, and allied with significant of a sort likely to be disconcerting to a probabilist." He goes on to point out that the heart has probably no significant influence whatever. This brief sketch of the book is sufficient to show that large amount of interesting scientific information it

The action of alcohol on man, of course, a subject which those who desire to avoid controversy leave alone; presumably controversy has no special terrors for the authors of this volume, and they will probably enjoy the storm which it appears to be raising. Unfortunately controversy and consequence public attention will probably concentrate on the least important passages in the book, for Professor Stenning has a neat turn of phrase and a pleasant sense of humour. We have already seen one review which concentrated its attack on the statement that teetotal dinners were apt to be dreary affairs!

Professor Stratford does not claim to speak with the same authority as he does the author of *Psychological Problems* and the other problems of psychology, but he does not speak with the same authority as the author of *Psychological Problems* and the other problems of psychology. He does not claim to speak with the same authority as he does the author of *Psychological Problems* and the other problems of psychology, but he does not speak with the same authority as the author of *Psychological Problems* and the other problems of psychology.

We are not prepared to agree with the author in all cases with regard to the relative emphasis he has laid on the various points that have to be considered in judging the action of alcohol on the community. Our chief criticism is that he hardly lays sufficient stress on the fact that alcohol is a habit-forming drug. Regarding this he writes:

"Every action which is sufficiently often repeated tends to become a habit, i.e., an overriding desire to take another dose as soon as the effects of the last begin to pass off. But this is not as marked as in the case of other drugs" (p. 151).

It is quite true that the habit formed for morphine

The first of these is the fact that the
 Commission has not yet received any
 information from the Government of
 the United Kingdom as to whether
 or not it is prepared to accept the
 Commission's proposals for the
 reform of the Common Market.
 This is a serious matter, for the
 Commission's proposals are the
 only ones which have been
 put forward by the Commission
 since the establishment of the
 Common Market. The Commission
 is therefore in a very difficult
 position, for it is unable to
 proceed with the reform of the
 Common Market until it has
 received a reply from the
 Government of the United Kingdom.
 The Commission is therefore
 in a very difficult position, for
 it is unable to proceed with the
 reform of the Common Market
 until it has received a reply from

 Kingdom.

alcohol habit if he regularly exceeds a certain very moderate amount of alcohol for any prolonged period.

As regards the economic aspects of the problem, Professor Chartling says:

"In a recent paper by Professor Collis it is pointed out that in the United Kingdom the expenditure on food per head comes to sixteen guineas, and on alcoholic drinks to eight guineas. In itself this amount spent by the whole country on alcohol does not seem disproportionate, if we consider that half of the total sum spent in alcohol reverts to the State and is used for carrying on the business of the nation. Moreover, alcoholic drinks supply the most widespread and of diminishing the tress and worries of the pleasure of the nation."

This is an example of an individual judgement that is likely to be holy contested. The statistic given would seem to be correct, that the average adult male spends more on alcohol than he does on his food, but many will think that this represents a wholly disproportionate expenditure on a single luxury. The chief disadvantage of these assumptions in controversial social problems is that they may divert attention from the remainder of the book, which is less controversial and of greater importance.

The book should be read by all those interested in temperance reform; they will do well to note the harm done to some of their supporters who have done their utmost for the cause, but for the most part are disappointed in the results; but now the friends of the alcoholists are as disappointed in the results of their abstemiousness as the temperance party were actively vocal, and as long as a writer confined himself to a study of alcoholists and abstemiousness, it is sure to be assailed by one or two bad sides. The authors, however, may console themselves with the thought of St. Paul, who contended that a controversial pamphlet by expressing the hope that his arguments were so entirely reasonable as to command the assent of both sides. „ But that is not to be hoped for, my next work should be that both might think me in the wrong; which I should understand as a purposeful injustice if it proceeded at least with impartiality and perhaps with truth.”

KALIA-AZAR.  
 NAYIR and AYER in their book on Kalia-Azar state that the peculiar local conditions which determine the endemicity of the disease can only be ascertained by the study of accurate statistics collected by those on the spot. It is more especially the questions to which investigation should be directed. The disease is stated to occur both in town and country, but chiefly in small compact villages surrounded by trees and decaying vegetable matter, and not in new villages. It is a site, house, and family infection. The exact mode of infection has not at present been discovered, but the possible means of infection are transmission from patient to patient, directly or through the agency of excretions or secretions, or transmission by the agency of a blood-sucking insect, directly or through man, or through an alternative host (bats, lizards), or infection directly to man from an insect in which the microbe is the natural flagellate. Spread of the infection is conceivably by the excretions, from the skin surface or by the peripheral blood through the agency of a blood-sucking insect. There is at present no proof that any one of these is the route used, but the most probable routes are considered to be by the peripheral blood or from the intestinal tract. In hospital, cases of Kalia-Azar are usually treated in the general wards, but no case of infection from the wards is known, although few hospitals respect the bed-bug is the most suspect, although the case against it is by no means proved. The authors give a graphic description of the symptoms of the disease, but state that a diagnosis on clinical grounds is seldom if ever justifiable. The less elaborate bedside laboratory methods of diagnosis include the triple test, the blood count and examination of blood films, splenic puncture, and blood culture. The aldehyde

medical supervision of these children. It would seem to me to be work admirably adapted to the inclinations and capacity of some of the religious sisterhoods of this country, and I am hoping to hear how the experiment has gone at St. Mary's, Broadstairs.

I think that it is along these lines that we could make the quickest advance and arrange for the treatment of these cases without much longer delay.

#### CONCLUSIONS.

I have now sketched out to you the problems of the great rheumatic disease as they appear to me at this time, and I have done my best to point out more particularly those factors which seem to me to be preventing us from coping more successfully with this disease of our country. I conclude by specifying the most urgent and important of the problems awaiting solution:

1. What is the underlying connexion between rheumatism and poverty? This I believe to be by far the most important question not yet certainly solved.

2. What is the origin of the repeated relapses and reinfections in the rheumatic state, and how can they be prevented?

3. How can we be enabled to give long courses of treatment to our many heart cripples in the hope of prolonging their lives?

It will be seen that these problems concern alike public health workers, clinical physicians, and that never failing friend of our profession—the charitable public.

#### DISCUSSION.

Dr. G. A. ALLAN (Glasgow) said that Dr. Miller had taken a wide survey of the subject and had outlined various avenues of attack against this most important branch of the problem of heart disease, and Dr. Allan was glad to find himself in general agreement with the attitude he had adopted. The object that was before the meeting was the prevention of that type of cardiac insufficiency which had its origin in the early years of life, and their attention was thus naturally directed in the first place to a consideration of acute rheumatism and its allies. The opener of the discussion had pictured for them the progress that had been made during the past fifty years in dealing with rheumatism and its cardiac effects, but it was a progress which, as he said, left rheumatism still one of the great serious infections of this country. The speaker wished to emphasize the magnitude of the problem that still confronted them. The returns of the Registrar-General were not sufficiently detailed to give accurate figures, but he found that in 1921, 53,710 deaths, or 11.7 per cent. of deaths at all ages and from all causes in England and Wales, were due to heart disease, and this did not include disease of the blood vessels. Tuberculosis and cancer, on account of which so much money was annually expended, appeared on the returns with about 10,000 less to their account. Many factors accounted for these stupendous figures, and not all of them were before them that morning, but they knew that rheumatism was one of the most potent single factors, and accounted for about one-half to one-third of the deaths due to heart disease in the wards of a general hospital. American figures were in close agreement with these, and in that country 11 per cent. of the total deaths were noted as being due to heart disease.

They could visualize the problem in another way by making use of the results of the medical inspection of school children. In Dr. Allan's own city of Glasgow, with a population of 1,111,428, the education authority was responsible for 198,304 children, and of those subjected to routine examination last year 0.6 per cent. had organic heart disease of the acquired variety, and 1.1 per cent. had functional heart disorder. In *The Health of the School Child*, which was the 1921 report of the Chief Medical Officer of the Board of Education, Sir George

Newman stated that in the routine examination of school children in England and Wales about 0.7 per cent. were found to have organic heart disease, and 0.8 per cent. had functional heart trouble, while in London, at the age of 12, 3 per cent. of the boys and 4 per cent. of the girls had "heart defects"—a term that probably included the functional cases. In other words, taking the smaller percentages, there must be in Great Britain between 45,000 and 50,000 children of school age who had organic heart disease, many of whom were destined to become cardiac cripples before middle life. An interesting point emerged from some figures supplied to Dr. Allan by Dr. Bruce, one of the school medical officers in Glasgow. In the 5- and 6-year groups of school children, 0.5 per cent. had organic heart disease; in the 13- and 14-year group 1 per cent. had heart disease. The percentage had doubled during the compulsory school period.

Dr. Allan declared that Dr. Miller had rightly put in the forefront of his paper the consideration of rheumatism as rheumatism. The control or prevention of acute rheumatism and its allies was the basic problem. Next there had to be considered the treatment of the child who had had rheumatism, chorea, or repeated tonsillitis, but who as yet had no cardiac lesion—the potential cardiac case. Lastly, there was the case of the child who had some cardiac lesion, but who was not yet in the category of chronic cardiac insufficiency. Any child beyond that stage did not at present come before them for consideration.

If possible, some agreement about the infecting agent was wanted—but an organism did not necessarily have to be seen before it could be fought. If they knew where it was entrenched they might be able to deal with it. What was the relation of tonsillitis to rheumatism? Was it simply in certain types one of the rheumatic manifestations, or was the tonsil the port of entry or the home of the organism? What was the relation of scarlet fever to heart disease? Did scarlet fever produce endocarditis, or did the rheumatic organism simply gain entrance through the diseased tonsil in that disease, and so produce arthritis and endocarditis? If some of these questions could be definitely settled it would obviate the necessity for some of the discussion regarding enucleation of tonsils in rheumatism. The subject of chorea could not be slipped in casually with rheumatism; it demanded separate and special consideration. Further, they did not know the conditions that predisposed to the rheumatic invasion. Dr. Miller called for an inquiry into the connexion between rheumatism and poverty. That was important, but it would not necessarily give all the information they wanted as to the predisposing factors. The whole question of predisposing factors should be the subject of systematic inquiry. Apart from all these questions to be solved they could, even at present, do something by education. In a letter from the author of the figures he had quoted there occurred the remark, "Parents do not realize that it is possible for children to have rheumatism." Parents could be made alive to certain aspects of the subject that might ensure earlier medical attention. Medical students should be made to realize the essential difference between rheumatism in the child and in the adult, and they and medical practitioners should be made to recognize that pharmacopoeial doses of salicylates, three times a day until fever disappeared, was frequently only playing with a serious disease.

The second class that should receive special mention was the child who had suffered from rheumatism, chorea, or repeated tonsillitis, but in whom the heart was not yet affected. The end-results that were met with in hospital or in private practice were not commonly the result of a single attack of rheumatism. Cases of pancarditis with a first attack did not as a rule live long. Could anything be done to prevent subsequent heart involvement, to prevent, that was, the recrudescence or reinfection? Dr. Allan referred to some work that had been done in this connexion under the auspices of the Association for the Prevention and Relief of Heart Disease of New York. A small series of 65 cases of potential heart disease had been followed and cared for over an average period of four and a half years; 24 had had rheumatic fever or growing pains,

The authors of the monograph under review are C. LINDGREN and D. D. VAN STREEK, names familiar to all who have had occasion to follow the work on blood gases, and the reasonable outcome of such a collaboration is a book of real scientific interest and of considerable ethical value. The thesis of the authors may be admirably presented in their own words: "Cyanosis appears to be chiefly dependent on two factors: first, the degree of hypoxemia; secondly, the extent of the compensatory changes which take place in the tissues of the body." It is a pity that the book does not contain more information relating to dairy and agricultural processes, but from the public health point of view such information has great practical importance, and this alone would have been of even greater value had it drawn more attention to the wholesome activities of bacteria of use in dairy work, agriculture, and industrial processes. With these additions it would have better deserved its title of a textbook of bacteriology for students of public health.

the absolute concentration of reduced haemoglobin in the blood, rather than on the ratio of reduced to oxygenated. About 5 grams of reduced haemoglobin per 100 g. of blood.

Dr. HENRY KAVATZ, of the science of finger-prints, upon which becoming yearly more important in the identification of dead bodies and in personal recognition for many civil purposes, such as registration of aliens, passports, and the identification of infants in orphanages, in addition to its use in criminal investigations. In the U. S. Army it is in general use, under the supervision of a large staff of trained experts. The system is of little utility unless two conditions are

may lie in a failure to oxygenate a part of the blood at all stages of its being side-tracked from venation. Rapid cyanosis is a condition which may be found in bronchopneumonia and in congenital heart disease with patent foramen ovale. The distinction is fundamental and of particular clinical importance. It follows immediately from the definition of cyanosis given above that only in the case of defective oxygenation of the whole blood can improvement be expected by giving oxygen. Many clinicians will find here an explanation of their puzzling experiences in the use of Dr. Fauld's apparatus. Dr. Fauld's apparatus was the first to log the finger-prints of, for instance, 500,000 soldiers in order. The importance of a satisfactory system of color-prints were fallacious and that the ten fingers of the person examined should be imprinted, and recorded in their proper order, was a discovery of the greatest importance. The subject of dactylography, early detected the essential features Dr. Fauld, who must be considered a pioneer in this branch of comparison. In both of these particular cases, when taken or catalogued in a manner to be readily available for comparison. In both of these particular cases, when taken or catalogued in a manner to be readily available for comparison. In both of these particular cases, when taken or catalogued in a manner to be readily available for comparison.

to elaborate a practical method of classification. His plan however, was not at the time (1866) considered at Scotland Yard because the system itself had not then been adopted and legalized. Dr. Faulds gives many interesting details of the history of finger-prints in ancient and modern times. In 1881 Bertillon published an account of his anthropometric system of identification: in 1894 a Government committee here considered in connexion with the causative and modifying

recommended a system combining finger-prints with Bertillon's method, and the suggestion was adopted in India three years later; in 1901 the ten-finger method was adopted in England; in 1914 Lord of Lyons drew attention to the permanent location of the pores of the skin as giving proof of personal identity. A description and classification of finger-prints in relation to the precautions and the fallacies to be guarded against in fingerprint research. The book is furnished with a good index and glossary and many illustrations.

A UGANDA TEXTBOOK OF MIDWIFERY.

For the 99·9 per cent. of our readers who are probably in the same quandary as ourselves in regard to this little volume let it be stated that an English preface reveals as an elementary textbook of midwifery in the Ljungskil language, for the use of the native students in the Ljungskil district. The nation composition there is divided towards our ideals without the aid of a policeman.

We hope, however, that some of us are able to walk straightly gives them steam to go forward to their higher destiny." straight and narrow line, whilst ethics, inspired by religion, function of law and its officers to keep on the Paul's evidently feels for the law, he says, "it is sublime to the needs of society explains the admiration that Dr. Franky at the outset that he is totally incapable of understanding a single word of it. In the interests of journalism it is seldom that such candour is admissible!

The author, who is 80 years old, is as keenly interested in his subject today as fifty years ago. It is possible that the successful application of his science of fingerprinting was no less than a revolution in the history of criminology. The author, who is 80 years old, is as keenly interested

appalling mortality of children and the appalling number of stillbirths amongst the scientific mothers. The

[illegible][illegible]

the tonsils as a preventive measure as soon after birth as possible. Then there would be no more rheumatism in children. With regard to secondary infection by way of the tonsils, in a child who had already had rheumatism and possibly had a damaged heart they knew that reinfection did not take place by this path, because enucleation of the tonsils did not prevent further attacks of rheumatism. On the other hand, septic tonsils must be adequately dealt with in the rheumatic as in the non-rheumatic child, just as carious teeth, rhinorrhoea, otorrhoea, and other foci of sepsis must be attended to on general principles. The more Dr. Emanuel saw of rheumatism in children, the more he saw that it resembled tuberculosis. In chronic tuberculosis, repeated reinfection took place from existing foci within the body, and so he believed it was with rheumatism—a second, third, and fourth attack of rheumatism in a child meant repeated infection from an existing focus in the muscles, joints, heart, or alimentary tract.

Given a case of subacute or acute rheumatism, had they any specific means of preventing a carditis? They had no specific antirheumatic serum, no specific vaccine. They were not serious in thinking that the heat of a fomentation, or the cold of an ice-bag, or the pain of a blister, or the terror inspired by leeches would prevent rheumatic infection of the heart. These therapeutic measures might have their use if only to give occupation to the nurse in attendance, but they could have no power in preventing infection of the heart.

What view were they to take to-day of the much vaunted drug sodium salicylate, introduced by Kolbe in 1876? It had been in use for forty-seven years—had it prevented endocarditis? They constantly came across diametrically opposite views. He read only a few weeks ago in the *JOURNAL* of the Association the serious recommendation to give sodium salicylate, 40 to 60 grains daily, for seven to ten days every month throughout adolescent life to prevent further reinfection of rheumatism. In contradistinction to that view, in the *Proceedings* of the Finnish Medical Society, Ehrstrom and Wahlberg pointed out that sodium salicylate could not be a specific remedy in spite of having steadily maintained that reputation for nearly half a century. Those authors compared, from their own hospital records, the incidence of rheumatic endocarditis in the thirty-four years preceding its introduction in 1876 with its incidence in the forty-four years following its introduction. They found that there was no evidence of diminution in the number of cases of rheumatic endocarditis. That was strong evidence that sodium salicylate was not a specific drug against rheumatism. Nevertheless, no one would deny that it was an extremely useful drug in the treatment of acute rheumatism, for it diminished both pyrexia and pain in a truly remarkable manner. Even in that, however, it was not a specific drug, for it reduced pain and pyrexia in other non-rheumatic infections. Unfortunately for the young rheumatic victim, the absence of pain in muscles and joints and even the absence of pyrexia as well did not mean the absence of cardiac infection. On the other hand, the presence of pain in muscles or joints and of pyrexia was strong presumptive evidence of cardiac infection.

While he did not wish to minimize the value of sodium salicylate in the treatment of a case of rheumatism with pain and pyrexia, he wished to point out that its very power of being able to relieve these symptoms carried with it a very real danger, for its use masked two of the important symptoms that should make them suspect rheumatic carditis. One of his colleagues had said to him before he left Birmingham: "I hope at Portsmouth you are going to denounce sodium salicylate as a cause of heart disease in young people." He would not go so far, but he did agree that sodium salicylate had its dangers, and in this wise: They saw a child in the hospital out-patient department with growing pains. They sent the child home and told the parent to keep it in bed for a month and they prescribed sodium salicylate. In a day or two the pains had gone, and the mother, regarding the child as cured, allowed it to get up. Had they sent the same child home to bed with a

have lasted longer, but the child possibly would have been kept in bed for the full month. The employment of sodium salicylate in rheumatism was comparable to the use of opium in a case of obscure abdominal pain. They would cure the pain, but mask a symptom that might be of the utmost importance. They had no specific against rheumatic infection of the heart and they must recognize the fact.

There could be little difference of opinion that this country was badly in need of some form of further provision for the prevention and treatment of heart disease in young people. Dr. Emanuel was no advocate, however, for copying New York. He did not want a society for the prevention of heart disease, nor convalescent homes and schools for cardiacs, nor special cardiac clinics, nor occupation bureaux for cardiacs. They did not want to focus attention on the heart; their aim must be the treatment and prevention of rheumatism. The crying necessity in this country was for hospitals auxiliary to existing general hospitals, where children with rheumatic manifestations might lie until all infection had ceased and where they could then remain until the damaged heart had been trained to respond to effort to its utmost capacity. To these auxiliary hospitals there would also be sent young people with well marked evidence of heart disease, but in whom there was no active infection. Having no active infection, they would not be sent in with the object of rest in bed, but to have their hearts trained to respond to effort. It would have to be a period of months, not weeks. It was essential that cases should be readily transferable from general to auxiliary hospital and back again without cumbersome machinery.

In the formation of these auxiliary hospitals two objects had to be kept in the foreground. (1) The education of the medical practitioner of the future—the medical student of to-day. Cases of rheumatism and heart disease in young people must not be drained away from the medical schools or else the medical student would go out into practice ignorant of this crippling disease, and he would be powerless to co-operate in the future in the prevention of a disease of which he would know nothing. That was no imaginary bogey, for it was exactly what was happening to-day with regard to pulmonary tuberculosis. (2) In regard to research, if they were to prevent heart disease they must prevent rheumatism, and to do this they must know a great deal more about the micro-organism of rheumatism, its site of entry into the system, whether repeated attacks of rheumatism meant fresh infections from without or repeated auto-infections from muscles, joints, heart, or alimentary tract. Lastly, they must know more of the relation between rheumatic endocarditis and so-called infective or malignant endocarditis. Investigations of this nature required clinical observations, plenty of cases, all stages of the disease from mild growing pains to fatal cases of infective endocarditis, bacteriological, pathological, biochemical investigations, x-ray and electrocardiograph examinations. The facilities and staff required for these investigations were already available at the general hospitals. It was therefore imperative, even if these auxiliary hospitals were paid for by the municipality, that they should be in the closest association with the general hospitals, where the facilities and staff required for research were already available, and where the medical practitioners of the future were being trained.

Dr. CAREY F. COOMBS (Bristol) differed from Dr. Emanuel as to the efficacy of salicylates in reducing the severity of cardiac rheumatism. A scrutiny of the notes taken at St. Mary's Hospital in cases under the late Sir William Broadbent showed that in the pre-salicylate period the cardiac lesions were more often severe and fatal than at the present time. Examination of the mortality records of Bristol showed that the incidence of fatal cardiac rheumatism was decreasing, but that the curve was falling less steeply than that of the general death rate. In that city, with a population of about 400,000, approximately eighty deaths occurred each year from rheumatic heart disease, and to this must be added the fact that in each case death was preceded by a period of crippledness averaging as much as ten years. It was the prevention of this mass of misery to which the Association was being invited, by Dr. Allan's

was confronted continually with two questions: (1) How long to keep the patients; and (2) how much rest to give them.

(1) With regard to the length of time required to prevent recrudescence of active symptoms, the experiment already referred to by Dr. G. A. Allan, where 65 cases of "potential cardiacs" were observed for average periods of four and a half years, led to the conclusion, amongst others, that no less than three years must elapse since the last recrudescence before a child could be regarded as reasonably safe from further relapse.<sup>1</sup> These children were presumably, however, treated while living in their homes, and it might be hoped that the influence of fresh air might be found to cut short such an extreme figure. Nevertheless, it seemed that they needed to take a longer view of the time element required to effect a cure in these cases, if they were to attempt to get better results than those which were at present obtained. So far, among 44 cases treated at Broadstairs, it had been possible to trace 19 children through periods of eighteen months; these cases remained at the seaside for periods varying from six weeks to twelve months, and were able to be re-examined after living normal active lives in London, attending the ordinary schools, for at least seven months. The results, if so small a number might be taken as any test, suggested that the children were subject to relapse in proportion to the shortness of their stay in the country; the longer they had stayed the less they seemed to have tended to relapse, and this to some extent independently of whether heart disease had originally been present or not. Thus, of 8 cases of "potential cardiac disease," in which the children had had true rheumatic symptoms—for example, rheumatic pains and chorea—without having had any cardiac involvement, and were kept for only short periods of from six to twelve weeks, because they had no symptoms or signs—of these 8 cases 5 had relapsed, 2 of them having acquired active carditis; whereas of 11 cases, who were kept from four to twelve months because they had signs of heart disease on their arrival at the seaside, only 2 had relapsed, and these were both with them for periods not exceeding five months. The remaining 9 had held their own. It seemed, then, to be a proposition worth examining that a great deal of time and money at present spent in the treatment of chronic heart disease would be saved if every child who ever had symptoms of the rheumatic state were sent into the country for periods of, say, six to eight months before being re-exposed to the environment in which they originally contracted the disease. Such a scheme incidentally offered the best chance of curing chorea.

(2) With regard to the amount of rest required by the children, everyone would deprecate any kind of routine rest; no one would wish, for example, to keep a child in bed merely because it had once had rheumatism or because it had a damaged heart. But there were a large number of cases which fell within the category defined by Sir James Mackenzie when he said, "So long as there is positive evidence of mischief, for example, a persistent increase of rate, a changing murmur, or a diastolic murmur which has arisen during the illness, the patient should be kept at rest, and this should be enjoined until the rate is quite normal, even although six months may elapse before that result is brought about."<sup>2</sup> And when one had excluded the rapid rate of the heart beat due to merely mechanical causes—for instance, extensive adherent pericardium—and the excitable pulse of certain neurotic children, there remained a number of cases in which the increased rate seemed solely due to the rheumatic poison, and in which a long period of complete rest, extending for as long as four months, had resulted in the assumption by the heart of a deliberate and quiet rhythm, which had been maintained on the patients being allowed gradually to get up, and had been found still to have been maintained on re-examination of the heart after seven months' active and normal life in London.

Dr. Raven did not agree that physical signs of the heart gave no indication of persisting infection. Abnormal signs alone were no indication, but where the abnormal signs were changing, even in a favourable direction,

then it was fair to assume that changes were taking place in the cardiac tissues, and that the stage of infective activity and tissue response to it had not been finally closed. Thus also, with time, systolic murmurs would disappear in some cases, and the area of cardiac dullness would diminish. But the sign most liable to change was the extremely common diastolic apical bruit described by Dr. Cheadle as the earliest sign of mitral stenosis.<sup>3</sup> That bruit appeared to be capable of observation and management of the greatest importance in the prevention of mitral stenosis; it was also very commonly associated with a persistently rapid heart beat. First occurring, as described by Dr. Cheadle, as a reduplicated second sound heard in the apex, it changed as disease progressed to a position in mid-diastole, and later still took on a prolonged pre-systolic character. Eventually, if untreated, this would tend to become the rumbling pre-systolic murmur of true mitral stenosis, but if treated by rest in an earlier stage it might be found in time to retrace these steps, first becoming mid-diastolic and then occurring as the apical reduplicated second sound. Finally, it might altogether disappear and remain absent on the patient's being allowed gradually to get up, and in four cases it had been found to be still in abeyance on re-examination of the heart after at least seven months' active life at home. In the light of this favourable sequence of events it seemed fair to suppose that the bruit was caused by disease of the mitral valve, and that the important thing was to allow the cusps of the valve, by sufficient rest, to return as far as might be possible towards their normal state, with a minimum of vascularization and cicatrix.

In the etiology of the disease it was of interest to inquire whether there might not be in the environment causing the original infection or recurrence a factor of infectiousness. The idea was not a new one; Newsholme<sup>4</sup> referred to acute rheumatism as an infectious disease having an epidemic prevalence with irregular periodicity, and recently in America figures had been brought forward in support of this possibility.<sup>5</sup> Dr. Raven was much struck with the disastrous effect of the introduction to his ward of a case of hitherto unrecognized and advanced heart disease; that boy had also an acute tonsillitis on admission, and was by mistake not isolated for about thirty-six hours. A nurse shortly after developed tonsillitis, and for some time afterwards they were troubled with recurring attacks of pyrexia in the children, only some of whom had tonsillitis, but in three of whom serious relapses occurred in the shape of recrudescence of the signs of mitral and pericardial disease, after they had made steady progress for many months or weeks.

Dr. F. G. LAYTON (Walsall) asked for a definition of the term "rheumatism," and for the evidence on which growing pains were regarded as a manifestation of rheumatic infection. When patients were ordered by a physician in the out-patient department of a hospital to go home to bed for a month, the general practitioner should always be written to and asked to supervise treatment and the administration of salicylate.

Dr. C. O. HAWTHORNE (London) agreed with Dr. Layton that to provide the term "rheumatism" with a satisfactory scientific definition was a task not easily accomplished. Yet surely no one doubted that clinical states to which such a name could be reasonably applied existed, and that for the most part these states could be recognized. In particular, these rheumatic manifestations in children were specially liable to be complicated with cardiac disease, and the main purpose of the discussion was to explore any method by which such a complication could be avoided. Institutions and organizations directed to the care of children after the mischief had been done were all quite admirable in their way, but no great gain could be expected unless prevention could be secured. He

Dr. ROUTH (Southsea) thought that there was too much fear in these meetings in looking at cases from the view of the expert or "specialist" rather than from that of the general practitioner. He was quite in agreement with the last speaker as regards the difficulty in tracing the cause of heart lesions in the young. In general practice acute rheumatism was a rare disease, though no doubt many cases of very mild rheumatic trouble were met with—so mild that they were not recognized as a streptococcal infection. In many cases tonsillitis was the only symptom, the parents being very averse from having their children's tonsils removed. He had at present under his care a child who suffered from repeated mild attacks of tonsillitis with slight pyrexia, each attack being accompanied by a transient mitral murmur which entirely disappeared with rest in bed and local treatment to the tonsils. There was a strong family history of rheumatism and the tonsils should certainly be removed. What struck him in private practice was the marvellous recuperative power of a child's heart and the way in which a heart apparently severely damaged might become perfectly normal in after years. As medical attendant at Uppingham School he met with boys who were sent to school as unable to play any games, but with carefully graduated exercise in a few years no heart trouble was discernible, and they could play football with perfect safety, and no bad after-effects were discovered. He thought that in many cases too much attention was paid to the condition of the heart and that children would do better if allowed to lead a more active life, careful watch, of course, being kept on them.

Dr. WITTINGTON (Hove) agreed with Dr. Attlee that properly regulated exercises were greatly to be preferred to depriving schoolboys of their games. When at Oxford thirty years ago he was told to give up rowing, but had he known as much then as he did now he would have preferred to have risked damaging his heart than to have given up rowing.

Dr. REGINALD MILLER, in reply, said he thought that Dr. Attlee's cases were not poisoned or infected hearts and should be treated on a nervous rather than on a cardiac basis. Swimming was not a satisfactory exercise for patients with functional cardiac disorders. He was glad there was general agreement as to necessity of rest, but too prolonged bed might be a drawback. Agreement also appeared to be general as to the value of salicylate treatment. It was satisfactory that the meeting felt the time had come for some investigation to take place, and it was the rheumatic side of the problem, and more especially its prevention, that must be stressed.

## SECTION OF LARYNGOLOGY AND OTOTOLOGY. E. B. WAGGETT, D.S.O., M.B., B.Ch., President.

### DISCUSSION ON SPASM OF THE LARYNX.

#### OPENING PAPER BY

SIR SCLAIR THOMSON, M.D.,  
London.

It is well, for the opener of a discussion to begin by studying, and then keeping his mind well fixed on, what a committee would call "the terms of reference." When I received the honour of an invitation to inaugurate the debate of this morning my first step was to turn to what I hope I may without conceit, call a well known English textbook. The first thing that struck me was that you can learn a good deal by reading your own writings! The second thing I had to find, by doing so, a confirmation of the observation made by Mr. Lloyd George in his recent speech at Oxford on July 22nd, when he remarked that "The fact is, in doing this, no, you discover how much more there is to be done."

Definition: "Larynx" or "Glottis."—Well, in St. Clair Thomson's book on *Diseases of the Nose and Throat*\* I

looked in vain, in the index and in the text, for "Spasm of the larynx." I found "Spasm" all right—but no spasm of "the larynx." I think that textbook is right; for I looked up "Larynx" in Stedman's *Medical Dictionary* (1921 edition) and there read that the larynx is the organ of voice production, and that "the walls of this organ are formed by nine cartilages connected by fibrous membranes, and the vocal cords, enveloped in folds of mucous membrane." All these structures do not share in the "spasm" we are studying, so I think the author of this textbook was nearer to exactitude when he referred to the matter in the index under the rubrics of "Glottis" and of "Spasm of the glottis." The larynx as a whole is not thrown into a spasm: it is the canal or thoroughfare of the voice-box which is closed spasmodically. It might be still nearer to correct definition if we called it "Spasm of the walls of the glottis."

Definition of "Spasm."—To be sure that we would all be agreed about the term "spasm," I turned to the same medical dictionary (Stedman's) and found the term defined as "an involuntary, convulsive, muscular contraction: convulsion, cramp." Another dictionary does not limit our conception to a very rigid or prolonged contraction, for it defines "spasm" as "a sudden but transitory contraction of a passage, canal or orifice."

#### CAUSES OF SPASM OF THE GLOTTIS.

The causes of glottic spasm may be:

- (1) Local irritation.
- (2) Irritation of the motor nerves.
- (3) Central nerve lesions.
- (4) Hysterical or functional disorder.

I. In the majority of everyday cases spasm of the glottis is a reflex phenomenon concerned with increased or diminished sensation in the pharynx or larynx. We will begin by systematizing these sensory causes.

#### Neuroses of Sensation in Glottic Spasm.

A. *Anaesthesia*.—There is much individual variety as to the degree of sensitiveness of the pharynx and larynx. It may be diminished (1) peripherally, by old age and anaemia, or by drugs (cocaine, orthoform, menthol, morphine, bromide, chloroform, and other anaesthetics), or by general affections like influenza, typhus, cholera, and pneumonia. It may be dulled (2) by affections of nerve trunks, as in the peripheral neuritis of diphtheria, or in cases where the superior laryngeal nerve (or its centre) shares, as often happens with motor paralysis of laryngeal muscles. Sensation may be reduced (3) by central affections such as the bulbar lesions of locomotor ataxia, general paralysis, glosso-labio-laryngeal paralysis, syringomyelia, multiple sclerosis, as well as haemorrhage, tumours, and gummata of the medulla. It occurs in a slight degree in hysteria and in epilepsy just before the seizure. These various causes lead to spasm by interfering with the sensation which watches over the glottis, to guard it from the ingress of foreign bodies or other irritants. We all know the sensation of a "crumb going the wrong way."

B. *Hyperaesthesia*.—But excessive or perverted sensation, by sending an exaggerated warning to the medulla, can also produce spasm. Amongst the causes of hyperaesthesia are many abnormal conditions of the general nervous system—anaemia, hysteria, neurasthenia, fatigue (physical, vocal, or mental), dyspepsia, excess of alcohol. Oversensitiveness is often present with acute or chronic laryngitis or pachydermia, and is also frequent at the menopause, in hypochondriacs, and in those who dread tubercle, syphilis, or cancer. Reflex causes of this hyperaesthesia may be traced occasionally to the various tonsils, the nose, ears, teeth, or the thyroid gland. It is, perhaps, most commonly met with as a very early indication of pulmonary tuberculosis. Many such cases go to the larynx, by itself, seldom to overlook them. Tubercle in the larynx, during a year or causes cough and spasm, any more than intrinsic cancer. It is quite usual to see a case where, during a year or more, a malignant growth has been steadily invading a whole vocal cord, without once having caused cough or spasm. Other frequent causes of hyperaesthesia—and hence

\*London: Cassell and Co., second edition, 1916.

1.—Medical Staffs of Voluntary Hospitals.  
In the work of voluntary hospitals, and for that  
the necessary qualifications and experience to per-  
form the work of voluntary hospitals, and for that  
an opportunity should be given to private practitioners  
to take part in the work of voluntary hospitals, and for that  
the necessary qualifications and experience to per-  
form the work of voluntary hospitals, and for that

XIV.—Representation on Boards of Management.  
The association of officially recognized representatives  
of the local medical profession in the promotion and general  
management of hospitals and other medical charities is desir-  
able in the interests of those institutions as well as of the  
profession, and that for the appointment of such repre-  
sentatives use should be made of the machinery afforded by a  
Division of the British Medical Association.

(b) *Long Representation.*  
32. Where representation of benefactors, subscribers, or con-  
tributors to the funds of a voluntary hospital is given on the  
board of management or governors of the hospital, representa-  
tion should be distributed so as to secure the representation  
of each interest in the hospital and so that no single interest  
should be in a majority. Contributions given with an implicit  
or explicit obligation of hospital service shall not rank for  
representation with other benefactions.

(a) *Medical Representation.*  
37. The association of officially recognized representatives  
of the local medical profession in the promotion and general  
management of hospitals and other medical charities is desir-  
able in the interests of those institutions as well as of the  
profession, and that for the appointment of such repre-  
sentatives use should be made of the machinery afforded by a  
Division of the British Medical Association.

39. No contributory scheme for hospital benefit should be  
considered satisfactory unless there are arrangements for an  
adequate home nursing and ambulance service, and for  
dental, laboratory, and x-ray facilities.

XVI.—Cottage Hospitals.  
40. As far as possible, every patient in a cottage hospital  
should have the right to be attended by his usual medical  
attendant.

XVII.—Admission of Cases to Cottage Hospitals.  
42. As it is necessary for the training in midwifery of  
medical students and pupil midwives that there should be an  
adequate supply of clinical material available for that pur-  
pose, no patient woman should be refused treatment in  
the obstetric department of a voluntary hospital or similar  
institution on the ground that she is eligible for a maternity  
benefit.

43. All women receiving treatment through the obstetric  
department of a voluntary hospital, or similar institution, who  
are entitled to a maternity benefit, should be required to pay  
such sum to the hospital or institution as shall be determined  
upon by the governing body.

44. From each such sum an amount, to be agreed upon between  
the governing body and medical staff, should be placed to a  
special fund, which shall belong to the medical staff.

APPENDIX II.  
THE BRITISH MEDICAL ASSOCIATION AND THE  
SOCIETY OF MEDICAL OFFICERS OF HEALTH.

REPORT OF CONFERENCE, HELD 1922-23, OF REPRESENTATIVES  
OF THE BRITISH MEDICAL ASSOCIATION AND OF THE  
SOCIETY OF MEDICAL OFFICERS OF HEALTH, AS TO PUBLIC  
HEALTH MEDICAL SERVICES.

I. The Conference has reviewed the obligations and powers  
imposed and conferred upon Local Authorities by Acts of  
Parliament in regard to Health Administration and the relative  
position of medical officers of health and general practitioners  
in schemes of health services. These obligations and powers  
include:

(a) *Medical survey or inspection.*  
II. Local Authorities must give effect to their legal obliga-  
tions. The extent to which they exercise their powers is in  
the discretion of the Local Authority subject to the prior  
approval of the appropriate Central Government Department.  
The Conference is of opinion that benefit would be likely to  
result from a closer co-operation of the local medical profession  
with the Local Authorities schemes of medical survey or inspec-  
tion and treatment.

III.—Recognition of Local Advisory Medical  
Committee.  
Every hospital area (e.g., the area of a voluntary  
committee), the Association, through its local

system showed no central lesion. On asking him, he reported that he had been attending several cases of whooping-cough, and I told him that his alarming symptoms were due to an irregular form of pertussis, that he would get quite well, and that I defied him to choke! This assurance, with some doses of bromide, and some chloroform at hand for inhalation, soon comforted him, and I was glad to have my diagnosis confirmed by Dr. Wilfred Harris and Dr. Buttar. For some fourteen days he willingly remained in bed as he found that the slightest exertion or a breath of cold air brought on an attack, although none was so severe as the first. Bacteriological examination of the slight sputum disclosed the pneumococcus but no Borget bacillus. The attacks gradually diminished, but continued for a month to six weeks.

**Glottic Spasm and Drug-taking.**—Attacks of functional glottic spasm may deceive the medical attendant, and the unjustified gravity with which he views the case generally adds to the severity of the attacks and the difficulty of curing them.

A young married lady, whose adenoids I had removed as a child and whom I knew as having a very bad family history of mental disease, developed, in the unwholesome atmosphere of life at Monte Carlo, attacks of glottic spasm. Under some trifling mental or physical stimulus (a discussion on "winning numbers"—save the mark!—or the inhalation of some extra cigarette smoke) she would spring from her chair, perhaps announce that "the chokes were coming," seize hold of a piece of furniture, or rush to the window for air, and then pass through the acts of what I have described as the "Phenomena of glottic spasm." She was watched by a devoted husband and an anxious maid. She was told that she might require a tracheotomy at any moment, and travelled to England with a cannula in her "vanity bag"! I found out that the husband, who had lived in the East, and had contracted malaria, not only was accustomed to give himself occasional doses of morphine, but, with that curious perversion of the drug-taker, so well described by Robert Hichens in his novel *Felix*, was gradually habituating his wife to the same vice. A little authoritative talk to both of them, and a sequestration of the tracheotomy tube, soon effected a cure. More than fifteen years have passed: the patient still moves in my horizon, but she has had no more "chokes."

**Epilepsy: Hydrocephalus.**—Whether the epileptic cry and the cry of hydrocephalus should be classed as examples of laryngo-spasm is, I think, very doubtful. They are certainly produced by involuntary, convulsive, and muscular action, and may be sudden and violent, so that they meet the terms of the definition of spasm I gave in our introduction. They are also produced in the larynx. But all this they do not differ from laughter, or screams of pain, or similar joyous or grievous sounds which we do not admit to the catalogue of glottic spasm.

**Laryngeal epilepsy** has perhaps received a disproportionate amount of attention, as it was first so fully studied by the great Charcot.

**Stammering.**—Severe stammering is sometimes accompanied by sudden explosive enunciation, but it can hardly come into our list. It is on an exaggerated expiration that the sound is made.

**ADDUCTOR SPASM OR ADDUCTOR PARESIS.**  
"When is glottic spasm not a spasm?" is a question which is far from being as trivial a matter as this way of putting it might suggest. When the vocal cords come together, either suddenly and temporarily, or gradually and more lastingly, we may be dealing with the resultant of one of two exactly opposite and opposing actions. This glottic closure may be a spasm caused by overaction of the muscles which close the glottis. A typical manifestation is that known to all of us when we "swallow the wrong way," or when some fumes directly irritate our arytenoidi postici. We remember that they are continuously acting all our life long, maintaining the thoroughfare of the larynx in that moderate degree of dilatation which we call "the position of quiet respiration," and which is midway between the position of complete adduction or approximation (that is, the position of phonation) and that of complete abduction (that is, the position of deep inspiration). When the "abductor tonus" fails appears—as it does when the abductor muscles fail (that is, in "complete abductor" or "recurrent paralysis") or when they cease for ever (namely, in death)—the vocal cords approach each other and fall into the position we all know as "the cadaveric position." Now this "cadaveric position" of paralysis is seen in

the laryngeal mirror to form very much the same picture as does tonic spasm of the cords. Both these opposite actions—manifesting themselves by an identical picture—are also subject to the addition of occasional spasm. The "recurrent paralysis" is seldom complete; some reduced glottic space is nearly always present and some mobility is still left in the adductor muscles, and hence spasm of a dangerous and not infrequently fatal form, is apt to be superadded. So with the primarily "spasmodic" condition: it, in the mirror, forms exactly the same picture—the cords are seen to remain near the cadaveric position, making no wide excursions outwards to the site of quiet respiration or beyond it to that of deep breathing. They may, in some cases, adduct normally and the voice is then preserved; in other cases their approximation is ineffective and we have functional aphonia; and in either we may get added spasm; but, however alarming it may look, it is not fatal, although in this the practitioner is often deceived. He is deceived because he is unprepared or untrained to distinguish between the two conditions—the paralytic and the spasmodic. Even experts are deceived. In our Section of Laryngology of the Royal Society of Medicine I have seen several cases shown as double abductor paralysis, and confirmed by some members. To others, with more clinical acumen, they were at once recognizable as cases of spasm, and this diagnosis was confirmed by the progress of the case.

I have known of cases of women with dysphonic voices for years, in whom no one had ever succeeded in seeing the cords separate widely. Yet it only required the employment of one or other well known remedy to secure this. One is, with the laryngeal mirror in position, to urge the patient to utter an uninterrupted and long-drawn "E." If this is continued until she is absolutely "breathless," the cords will be seen to fly wide apart as, with a loud pant, she refills her empty chest. If this fails, one may succeed in seeing the same result by tickling her pharynx with the mirror, by blowing in some irritant vapour or powder, or by suggestion in various ways. I have known all these fail, and the diagnosis only settled, objectively, by placing the patient under a general anaesthetic.

Of course the narrowed glottis of this latter group is caused by adductor contraction, and any superadded spasm (that is, complete closure) is free from danger; for it only requires a certain degree of asphyxia to stimulate the intact cords to fly apart. In the former group the narrowing of the glottis is caused by true organic paralysis of the glottis-opening muscles; any addition to the permanently and irrevocably reduced ration of respiration may produce an asphyxia which may be fatal.

**Semon's Law.**—We remember that in true organic paralysis of intrinsic muscles of the larynx it is the opening, or abductor, muscles which are the first to go (Semon's law), while the adductors survive a long time. We are taught that in functional disease the reverse occurs: it is the glottis-closers which are the first to go and the openers which remain acting. This conclusion is illustrated by the well known condition of functional hysterical aphonia, and it is generally the rule. But I have often wondered if this rule, so far as it refers to functional cases, is constant. For, to return to my query "When is glottic spasm not a spasm?" I assure you that it is not an indifferent and merely academical question. Our treatment of a case of intermittent stenosis of the glottis should be very different according to the conclusion we arrive at—if we reach one. Thus a parietic condition requires tonic, stimulating, irritative treatment; while a spasmodic condition demands the opposite line of relief—namely, the administration of sedatives and anaesthetics. The one condition may even be caused by a drug which relieves the other!

The "Spasm" of General Anaesthesia.—What is the contracted glottis and occasional clonic or tonic closure of general anaesthesia due to? Is it spasm and tonic action of the adductor muscles, or is it a paresis of the abductor (postici) muscles, or a temporary abrogation of that abductor tonus which is constant through physiological life? Anyhow, the lesion is a central one, due to the

— — — — —

The manuscript was read on January 21st, in the Colonial Medical Library, with Dr. A. J. David in the chair. The president delivered his inaugural address on pharmacology, and a vote of thanks to him was carried unanimously. A meeting of the Branch was held on February 12th, with Dr. A. J. Nell president-elect, in the chair, when Dr. L. de Silva read a paper on chronic nephritis in a cat, and showed microscopical specimens; the paper was discussed by Dr. W. L. de Silva, Dr. I. David, and Dr. A. J. Nell. A meeting of the Branch was held on March 14th, with Dr. I. David, president, in the chair, when Dr. L. de Silva read a paper on diabetes mellitus in Ceylon, with an analysis of 60 selected cases. A meeting of the Branch was held on May 16th, with Dr. I. David, president, in the chair, when Dr. L. Nicholls read a paper on

means of sprays of 4 per cent. cocaine. I have substituted for this eucaine with adrenaline. The local irritation probably acts only in the presence of such hyperexcitability of the cerebral centres as exists in the subjects of tabes dorsalis, the centres being probably those in the medulla. The laryngeal spasm producing the ictus laryngis, or so-called "laryngeal vertigo," has some points of interest. The patient feels a tickling in the throat, proceeds to give a slight cough, and finds himself on the ground. This has generally been attributed to a sudden congestion of the nervous centres produced by the pressure resulting from the expiratory effort accompanying the cough. My view is that the preliminary to the cough is an inspiration, and if this is accompanied by a closure of the glottis expansion of the thorax occurs without the entrance of air. The organs in the thorax expand and draw in blood. This causes some degree of drain on the cerebral circulation, which under certain conditions leads to a momentary anaemia of the brain and a sudden syncope, during which the patient loses consciousness and falls to the ground. Close questioning of the patients has convinced me that this is the actual course of events; I therefore prefer the term "laryngeal syncope" to that of "laryngeal vertigo." Why does this not occur much more frequently? In persons with normal arteries these adapt themselves to the change in pressure, but if there is loss of elasticity from arterio-sclerosis the adaptation is slow or incomplete, and syncope occurs. Those of my patients who have experienced this stroke have mostly been the subjects of gout and arterio-sclerosis. I believe, however, that in one case the main factor was instability of the vasomotor system, with neurasthenia due to overwork.

Sir StClair Thomson's inclusion of the glosso-pharyngeal nerve among those influencing the larynx is of interest in view of its share in the innervation of the tonsils and the lingual tonsil. The superior laryngeal also sends small branches to the lingual tonsil, and I look upon this region as almost a "motor point" for the larynx. I have frequently restored the voice in functional or simulated aphonia by applying faradism to the region of the lingual tonsil.

W. H. KELSON, M.D., F.R.C.S.,  
Surgeon, Throat Hospital, Golden Square.

It is impossible and unnecessary for me to deal with many of the points so ably raised and dealt with by the previous speakers this morning, but I will just touch on a few. I would, however, submit, in the first place, that the term "spasm of the larynx" is a little unfortunate, though in common use; for the larynx consists mainly of a partially ossified cartilaginous box or skeleton. If, however, we shift our position and speak of spasm of the glottis, we must remember that there is a false glottis between the ventricular bands as well as the true one between the true cords, and that this at times becomes spasmodically closed.

The compensatory mechanism by which one group of muscles gives kindly help to another when for some reason this latter is more or less put out of action is shown very well in the larynx, the false cords coming to the assistance of the true.

Possibly the term "spasmodic closure of the laryngeal airway," though cumbersome, might be correct.

The words "adductor" and "abductor" are so very similar both vocally and in print, that mistakes are apt to occur, and so I shall to-day, for clearness' sake, in my remarks, substitute the word "constrictor" for "adductor."

Although there may conceivably be spasm of the abductors alone, and it is often difficult to say whether there be spasm of a certain group of muscles or paresis or paralysis of its opponents, yet in either case the result will not be to reduce the airway, with the alarming symptoms one gets in constrictor spasm. The term "spasm of the larynx" as commonly used refers to this only—obviously a much slighter spasm of the constrictors will produce dangerous symptoms if the abductors be

paralysed. The muscles which close the airway in the larynx are stronger than those which open it, therefore the tendency of any nerve irritation, whether direct or reflex, is to cause closure, and the excitability of the reflex mechanism being much more marked in children, attacks are more easily produced in them, especially at night when the higher controlling cerebro-cortical centres are in abeyance. We are all familiar with the spasm coming on in the inflamed larynx of false croup, and that set up by the introduction of the tip of the finger into the post-nasal space of a lightly anaesthetized child; any condition keeping up irritation in the larynx predisposes to spasm. In a child with papillomata under my care any excitement brings on an attack. Of underlying morbid conditions tending to spasm, rickets appears to be the commonest: the plausible suggestion has been made that the laryngeal attacks are analogous to asthma—the spasm attacking the larynx instead of the bronchioles. The examination of the larynx of a restless infant is by no means easy, and we find mistakes being made by most astute observers; for example, the so-called "congenital laryngeal stridor," of infants was described as due to spasm till shown to be produced by other causes. I happened to be working under Dr. Lack when he and Dr. Sutherland were investigating this affection, and had the advantage of seeing many of the cases; these showed clearly that the stridor was due to a collapsing of the too soft epiglottis and aryepiglottic folds, owing to developmental deficiency, which as time went on gradually disappeared.

In older children one meets with laryngismus stridulus, the phenomena of which have also been attributed to laryngeal spasm, but which has been more correctly described by Rehn as a spastic symptom-complex, and he says that, examination of the larynx being out of the question during an attack, the diagnosis as to spasm of the glottis is only speculative. Two remarkable cases of what appeared to be spasm of the glottis were reported in the BRITISH MEDICAL JOURNAL in 1898. Two children, apparently healthy, died within a few days of each other, the post-mortem examinations revealing rickets only. In both cases the faces became suddenly blue and the bodies rigid, but no sound was uttered. It is not stated whether a foreign body was sought for. I once lost a patient, a child on whom tracheotomy had been performed ten days before. A nurse removed the outer tube, and the patient became blue and stiff, and died before it could be replaced. The post-mortem examination revealed congestion of the larynx only.

A rather interesting question arises as to whether simple spasm of the glottis—that is to say, when uncomplicated by other obstruction, such as blood clot or swelling—is ever directly fatal; personally I have never seen it. Passing on to laryngeal spasm in older persons we come to a wide range of affections, in many of which the central nervous system takes an obvious part; but the only one on which I shall touch for a moment is the hysterical form, and in this spasm and bad muscular balancing and inco-ordination seem to run riot. In the BRITISH MEDICAL JOURNAL (1871) a striking case is recorded of loud stridor, both expiratory and inspiratory, in a woman of 24, who had previously presented various hysterical phenomena. On laryngoscopic examination the glottis was seen to be partially closed during inspiration by irregular muscular action. On putting the patient under chloroform the noise ceased, but returned with the return to consciousness. After the administration of a few doses of chloral the stridor ceased, but was replaced by aphonia.

One case of this kind I shall always remember. Some years ago a girl, who emitted a very loud, unpleasant, high-pitched stridor both with expiration and inspiration, was shown at the Medical Society of London. The attacks were continuous but came on at any time and without any apparent exciting cause. The late Sir Stephen Mackenzie diagnosed the case as hysterical, and, undertaking to cure her, took her into the London Hospital. The treatment consisted of galvanism, which I as his house-physician had to apply to the throat whenever the noise started, day or night. This was done, and she left apparently cured after six weeks in hospital.

## ACUTE INTUSSUSCEPTION IN AN INFANT: RESECTION: RECOVERY.

On June 19th, 1923, I was called out by Dr. Garner of Birkenhead to see a small patient of his. The infant was a girl, three months old, who until the present illness had been in excellent health.

On the previous day there had been a sudden attack of abdominal colic, intermittent in type, accompanied by screaming, which some hours later was followed by the passing of a small amount of blood per rectum. The colic continued, and later much blood was passed. The colic ceased and the child became quiet, but as the haemorrhage continued the parents became alarmed and during the night called in their doctor. The infant was now very quiet, and as it was still losing blood he plugged the rectum. He saw the child again later, when it looked very ill; the haemorrhage had stopped, but it had been vomiting at intervals during the early morning. When we saw the child about 9.30 a.m. the eyes were sunken, the face blanched, and it took notice of neither parents nor strangers. The screaming had long since stopped, and it was abnormally quiet. Abdominal and rectal examination revealed a large tumour in the left flank. Intussusception was diagnosed and immediate operation advised.

The operation was carried out through the usual incision. A large intussusception was found extending into the pelvic colon, which was easily reducible as far as the splenic flexure. Reduction then was very difficult, and after a further two inches or so had been dealt with became impossible. On making further attempts to effect reduction the bowel wall commenced to split. I decided to resect the whole remaining mass and perform a lateral anastomosis. This resection included the last six inches of ileum, the caecum, ascending colon, and about half the transverse colon. On examining the specimen afterwards the intussusception was seen to be a double one; the last one and a half inches of ileum had projected through the ileo-caecal valve, and the remainder of the intussusception was made up of caecum and colon, with the ileo-caecal valve and this projection as its apex. The terminal portion of ileum, the caecum, and part of the ascending colon were gangrenous. This child made an uneventful recovery, left hospital fourteen days after operation, and is now perfectly well. The case is most instructive on account of its rapid progress; careful inquiry elicited the fact that the condition had barely lasted twenty-four hours from onset to operation.

Liverpool.

## LARGE PLEURAL EFFUSION.

It would be interesting to know what amount of fluid has been drawn from the pleura on the left side, as lately I have had under treatment a man, aged 36, who helped his father, a farmer, and called me in at the end of May owing to cough and breathlessness. He had been ailing since January or February with a cold and cough. He put it down to the cold and wet weather, and worked more or less all the time.

When I saw him his expression was anxious, and he was suffering from shallow breathing and slight cough. The temperature was normal, and the pulse 76, small and regular. I found the heart beating under the right nipple and dullness all over the left thoracic cavity. He was tapped, and one and a half pints drawn off. As the needle got blocked no more was taken then. Four days afterwards, in the cottage hospital, he was again tapped, and six pint-measured drawn off.

After the operation he acknowledged he felt a bit better; no doubt he did. To have seven and a half pints of serum in the left thoracic cavity and to be able to get about and do any work seems impossible. At the present time he is gently getting about and helping with the milking. His complexion is much improved, and he eats and sleeps well. The heart has gone back to the left side; breath sounds are feeble; cavity tympanitic and voice sounds heard everywhere.

Is my case a unique one in the quantity of fluid evacuated? The prognosis in such a case is interesting; at present all is going well, and with the Buxton atmosphere we hope for the best.

## Reviews.

### THE ACTION OF ALCOHOL ON MAN.

In writing *The Action of Alcohol on Man* the aim of Professor E. H. STARLING has been to give an impartial account of the effects of alcohol on man in language intelligible to the general public. In the main portion of the book Professor Starling describes the pharmacological actions of alcohol; he then discusses the influence of alcohol on the community, and finally sums up his conclusions in a chapter of sixteen pages. The last third of the book consists of three appendices; in the first Dr. ROBERT HUTCHINSON describes the use of alcohol as a medicine, in the second Sir FREDERICK W. MOTT gives an account of the relation between alcohol and insanity, and in the third Professor RAYMOND PEARL of Johns Hopkins University, Baltimore, analyses the statistical evidence as to the influence of alcohol on the duration of life.

The account given by Professor Starling of the pharmacological actions of alcohol is a lucid and impartial exposition of a highly complex problem. He describes the action of alcohol on each system of the body in turn, and begins each chapter with a clear and concise account of the physiology of the system described. The main facts regarding the action of alcohol are set forth, and the author not only states the chief experimental results obtained but also points out what these results really prove concerning the influence of alcohol in ordinary life.

The writing of an approximately accurate account of the simplest physiological subject without assuming any physiological knowledge on the part of the reader is, of course, a very difficult task, but the author has done more than this for he has given an extremely accurate account of a complex pharmacological problem every point in which has been obscured by controversy.

The main conclusions regarding the actions of alcohol are roughly as follows: Alcohol is a food which is absorbed exceptionally rapidly and easily, but its use by the body is hampered by certain important limitations. As regards the drug-like effects of alcohol,

"apart from the results of chronic overindulgence in strong alcoholic fluids, the only action which is significant is its action on the central nervous system. . . . The action of alcohol from beginning to end is essentially depressant. . . . In the first place we can say that it is unsuitable for the highest mental efforts, or during the performance of prolonged muscular feats."

It is held, on the other hand, that in the less strenuous moments of life the mild narcotic action of alcohol may be of considerable service in conducting to repose and assisting digestion by promoting tranquillity. The immoderate use of alcohol is, of course, condemned, and immoderate use is defined as that which diminishes a man's efficiency and powers of performing his normal avocations. The limits of moderation are set at a regular ration of about a glass of wine or beer for lunch, and half a bottle of light wine or three ounces of whisky in the evening. It is considered probable that these amounts can be doubled on occasions without harm, but that the increased quantity will probably diminish a man's efficiency the next day. This account of the pharmacological actions of alcohol is quite unprejudiced and gives a perfectly fair selection of all the main work done on the subject; the chief conclusions would, we believe, be subscribed to by the great majority of those who have studied the question.

The appendix by Sir Frederick W. Mott on alcohol and mental disorders is interesting as he incidentally reveals many errors in asylum statistics; he concludes that "alcohol plays a relatively unimportant part in the production of certified insanity," but points out that all the evidence indicates that a mental deficient is made drunk by extremely small quantities of alcohol, and hence most mental deficients who have access to alcohol get the reputation of drunkards although they may consume very little.

*The Action of Alcohol on Man.* By E. H. Starling, R. Hutchinson, Sir Frederick W. Mott, and Raymond Pearl. London: Longmans, Green & Co. 1923. (Demy 8vo, pp. vi+231; 5 figures. 12s. 6d. net.)

phere, but from time to time and year by year in the resolution was put to the meeting, G. Lloyd, who had spoken earlier in favour of the resolution if it was still possible, asked for an investigation from the chair that if the resolution were carried from the point of view of the public, and that it was possible in their resignations, every possible aid still be made to settle the matter by negotiation. Mr. Lloyd assured the questioner that everything possible in this direction would be done. He rose to ask a question, and was greeted with cries of "Vote!" He desired to know whether, for this resolution, a practitioner was committing the sending in of his resignation. Mr. Lloyd said: "I consider he would be doing so." Mr. Lloyd, expressing the opinion that the remuneration was inadequate, urged the Panel Committee and Insurance Acts Committee in every way possible an increased offer, and pledging loyal support to the Committee in this direction, was then put and resolved. There were no dissentients, and it was stated that practitioners present numbered 650.

## MEETING OF BUCKINGHAMSHIRE PRACTITIONERS.

Address by THE MEDICAL SECRETARY.

Mr. Alfred Cox, attended on Friday, 12th, a meeting called by the Buckinghamshire Association of the British Medical Association of all the practitioners in the county and on the county panel. Dr. J. F. Chesham, Chairman of the Division, was in the chair. ## REVIEWS.

test is that from which most valuable information can be gathered and is the easiest to perform. If this reaction is strongly positive no further confirmation is required. A drop of 30 per cent. formaldehyde is added to 1 c.cm. of serum; in a well established case of kala-azar the serum will immediately set like white of egg, and the reaction is considered as absolutely diagnostic of the disease. The blood count is regarded by some as characteristic; there is marked leucopenia and a great reduction in the proportion of white to red cells. The parasite is present in the peripheral blood and by careful examination of blood films can be detected in nearly 100 per cent. of the cases. Blood culture on blood-agar gives equally good results. The authors furnish complete directions for carrying out these various diagnostic tests. The specific treatment of the disease consists in the intravenous injection of the sodium salt of tartaric acid, and cure may be anticipated in 95 per cent. of the cases, provided that the disease is not too advanced and that none of the more serious complications have developed. With regard to the duration of treatment a general rule is suggested, that if the temperature becomes normal in two weeks the treatment should be continued for two months; if in three weeks, for three months; if in four weeks for four months.

## GONORRHOEA: BACTERIOLOGY AND TREATMENT.

THE book on *Gonorrhoea* by DAVID THOMSON is the outcome of seven years' work by the author on the bacteriology of this disease. The author states that it was originally his intention to publish a series of papers dealing with the subject but that so much data accumulated that it became necessary to bring the information together in a book. In order to complete the work and to render it of greater value to the practitioner, the collaboration of various clinical workers was invited and chapters added on the abortive treatment of gonorrhoea and the clinical manifestations and modern treatment of the disease. The result is a very complete work on the subject, certainly the most complete that has yet appeared from a British author.

Perhaps the most remarkable feature in the book is the wide range of its references to foreign literature. In all some 2,000 of these appear, so that the work should be of the greatest value to anyone in search of the literature of any aspect of gonorrhoea. It is, however, in the main a treatise on the bacteriology of the disease and two-thirds of the book deal with laboratory methods. Few bacteriologists are more competent to deal with this subject than Dr. David Thomson, and his chapters on the cultivation of the gonococcus, its toxins, and the secondary organisms that are commonly associated with it, are excellent.

In a later chapter the author deals very fully with the question of immunization by means of vaccine therapy. He is strongly in favour of the use of specific vaccines in attaining this object, and although he is prepared to admit that the injection of foreign or non-specific proteins, such as typhoid bacilli, may bring about improvement, he considers that still greater benefit would have been obtained by the use of a vaccine that was specific. The same shock will be produced in the latter case if only a sufficient dose is given and specific antisubstances will have been formed. The fact that good results have been obtained by the use of the injections of typhoid bacilli may, he considers, be explained on the supposition that the chemical composition of typhoid germs resembles that of gonococci, both organisms being Gram-negative and easily soluble in weak alkali. The antisubstances formed against the one are, therefore, likely to act to a great extent as antibodies against the other.

In another chapter a full account is given of the author's work on detoxicated vaccines and replies are furnished to the criticisms usually levelled against this class of vaccine. More particularly is an answer given to the objection that a non-toxic substance which produces no reaction when injected is unlikely to produce antisubstances. In his

opinion the toxic substances removed from gonococci by his process of detoxication are simple nitrogenous protein products that are of relatively little value in immunity. He states that these toxic products do not act antigenically when used in the complement fixation test, and that they are not to be compared with true exotoxins such as the toxins of diphtheria and tetanus bacilli. These true toxins, unlike the simple products removed in the process of detoxication, are precipitated by alcohol, and are highly complex protein substances resembling more those found in snake venom. However, in his later researches the author has avoided the use of strong chemicals and has prepared detoxicated vaccines with weaker alkalis. A short chapter on vaccine treatment in gonorrhoea has been contributed by Dr. Kenneth MacLachlan and chapters on infection, incubation, and abortive treatment by Mr. Claude Mills.

Part VI, on the clinical manifestations in the practical modern treatment of gonorrhoea, has been written by Dr. David Lees, lecturer and director of the Venereal Diseases Clinic, Edinburgh. These chapters are eminently practical and will render the book of greater value to those looking at gonorrhoea from the point of the clinician rather than of the bacteriologist. The illustrations, including some coloured plates, are excellent, and both author and publishers are to be congratulated on the way in which the book has been turned out.

## A TEXTBOOK OF BACTERIOLOGY.

THE fifth edition of the *Textbook of Bacteriology*,<sup>4</sup> originally written by HISS and ZINSSER and published in 1910, although following the early plan fairly closely is a larger volume than its predecessors and contains also a section dealing with pathogenic protozoa, written by Dr. FREDERICK RUSSELL. The book has been almost completely rewritten, the aim of the authors being to correlate bacteriological knowledge with the branches of medicine and prophylaxis to which it is most directly applicable. Being designed to supply the needs of both students and practitioners of public health as well as medicine, the book includes clinical and epidemiological data not usually found in textbooks of bacteriology; there is a section also dealing with infection and immunity. How well the authors have succeeded in keeping their textbook up to date may be exemplified by the fact that six pages are devoted to the so-called "bacteriophage" phenomenon of Twort and d'Herelle, and the recent work of Bordet and Ciuca is critically reviewed. The observations of Kruse and others, suggesting that the common cold is due to a filtrable virus, are also mentioned.

This book will be of more value to graduates working for higher degrees in medicine and for diplomas in public health than to the ordinary medical student. The needs of the latter are catered for by many excellent books of smaller dimensions and a more moderate price, and since the science of microbiology is advancing so rapidly it is not wise to recommend the medical student to purchase a volume which he will probably not find time to read during his student days. To those working for the D.P.H., on the other hand, the book will be very useful because of its broad and generous scope and because it deals with the origin and spread of epidemics. Previous editions have been very popular with D.P.H. students, and the fifth edition deserves the same regard.

It cannot be maintained, however, that the customary method of supplying to advanced students information about unicellular plants and animals is satisfactory from the scientific point of view. The activities of bacteria are being studied by medical, sanitary, agricultural, and industrial bacteriologists, and authorities in each of these departments write learned treatises on the organisms which happen to be of interest in their particular province and neglect those with which they have no immediate concern. It might be said, of course, that those readers for whom the present volume has been written would not

<sup>4</sup> *Gonorrhoea*. By David Thomson, O.B.E., M.B., Ch.B. Edin., D.P.H. Camb., with contributions by David Lees, D.S.O., M.D., F.R.C.S.E., Claude H. Mills, M.R.C.S. Eng., L.R.C.P. Lond., Robert Thomson, M.B., Ch.B. Edin., Kenneth MacLachlan, M.B., Ch.B. Edin., Oxford Medical Publications, London. H. Frowde, and Hodder and Stoughton. 1923. (Double cr. 8vo, pp. xiv + 519; 19 plates, 22 figures. 12 2s. net.)

<sup>4</sup> *Textbook of Bacteriology*. By Hans Zinsser, M.D., with a section on Pathogenic Protozoa by F. F. Russell, M.D. Fifth edition. New York and London: D. Appleton and Co. 1922. (Demy 8vo, pp. xiv + 1135; 164 figures. 35s. net.)

group for administrative purposes excessive budget-ness, habit spasm, and Sydenham's chorea, but this suggestion should not be allowed to obscure the more important issue and the clear connexion that exists between rheumatic chorea and heart disease. The conditions which predispose to rheumatic chorea are not necessarily the same as those which produce articular rheumatism, and the etiological factors would have to be investigated along parallel but not necessarily identical lines. Prone to relapse, and when involving specially liable to be followed by cardiac involvement, it is one of the serious and intractable disabilities of childhood.

Difference of opinion exists as to the criteria which should be used to determine the cessation of the active period of the rheumatic infection in the child. This is a matter which ought to be settled, as it is very important in its relation to heart involvement and possibly also to the question of reinfection or recrudescence. Some have argued that the milder nature of the joint pains in the child as compared with the adult, and their speedy disappearance under the action of salicylates, are really factors which endanger the child's heart, because the child, being free from pain, may be allowed up sooner than the adult, whose more severe pains keep him in bed for a longer period; the more frequent involvement of the heart in the child than in the adult may thus, it is thought, be explained. Rheumatic fever is not in essence a simple joint infection, and it is doubtful if these arguments go to the root of the matter. The presence of blood vessels in the valves of the child's heart and their disappearance during early adult life, as has been demonstrated by Gross in his work on the *Blood Supply to the Heart*, affords a reader explanation. From figures reported in the discussion and from others that we quoted in a previous article (June 2nd, p. 942) it would certainly appear that the liability to relapse is definitely lessened by prolonged after-care or convalescence in the country under suitable conditions.

This raises the question of the provision of convalescent hospitals or cardiac homes where convalescent rheumatic children, with or without heart lesions, can be kept for periods of months. There are a very few in this country, but the experience at Broadstairs, though based on too few cases to justify a definite conclusion, seems to point to the fact that a residence of months rather than a period measured in weeks should be aimed at. It would appear that the much higher incidence of heart disease in rheumatic children of the hospital class as compared with outpatients for prolonged convalescence. Thus while at Broadstairs about 1 per cent. of the boys give a history of rheumatic infection, organic heart disease is practically unknown. The hospitals cannot supply the lengthy treatment required, nor are they the ideal places for recovery in the later stages. A similar remark applies to the ordinary convalescent homes, even those which admit such cases at all; not are the majority of those which do prepared to keep the child for a sufficiently long period to be of practical value. Not a little attention was paid to this aspect of the subject at Portsmouth. Dr. Miller advocates special heart homes as the ideal. The reports from the few that have been opened in this country are encouraging. The convalescent care of cardiac and potential cardiac cases has been a special feature of the New York scheme, and there are now available about 400 beds

## THE PREVENTION OF HEART DISEASE.

SATURDAY, OCTOBER 20TH, 1923.

### THE PREVENTION OF HEART DISEASE.

BRITISH MEDICAL JOURNAL.

1000

British Medical Association addressed itself to one of the major medical problems of this country when it took up the discussion on the control of heart disease in its early life. The report of the discussion will be found in this issue (p. 702), and the consensus of opinion points to a progress in the past so slow as to warrant special inquiry into the disease. The steps to be adopted to combat the disease. The subject for discussion was by definition limited to the aetiology and treatment of heart disease in early life, and it was therefore mainly directed to the rheumatic child. It is at first sight difficult to understand why little has been done to combat the ravages of rheumatism in childhood when its later effects are so well known. Whether it be that the introduction of a stethoscope, as Sir James Mackenzie has suggested, or the more careful search into the morbid anatomy, or the greater attention that has been devoted to the intrinsic cardiac mechanism, has delayed at different times the minds of those interested in cardiac problems from preventive measures, it is not to speculate. Rheumatism has been assumed to be one of the diseases associated with our country climate, and rheumatic heart disease has been accepted as a natural corollary. Several influences have fortunately at work to terminate this attitude of passive acceptance of conditions which may prove, in large measure at least, to be remediable. The General Medical Council is preaching that the importance of prevention should be impressed on the medical student; the Ministry of Health pleads "for new attitude toward heart disease which shall be a logical and prophylactic in spirit"; the example of New York, with its elaborate scheme for the prevention and relief of heart disease, has aroused thought; a very excellence of the work that has been done in aspect of the diagnosis of cardiac disease and the rhythmias has awakened workers to the fact that prevention must be sought along other lines. What-er be the determining factor there can be no doubt an awakened interest in the study of heart disease and the preventive aspect, and the Section of the Association has asked the Council to inquire into the appointment of a special committee to combat the grave menace to the country arising from this cause.

In that type of heart disease which has its origin in some form is the most frequent cause, real-early life, and of which, therefore, rheumatic infection must deal with the prophylaxis of that prevention *per se*. Certain points raised in the discussion call for a full investigation. Among them are a predominating incidence of rheumatism among the over classes, the advantage of prolonged residence in fresh air and sunshine during convalescence in fighting against the tendency to relapse, the habit of the organism, and the relation of tonsillitis to the ease. Again, the close relationship between chorea and rheumatism is generally recognized. Dr. Forrester, in an article on the care of the choreic child published this week (p. 700), has included in one

of all possible respect. Antivenereal treatment on a national scale has been applied during the last three years, and since 1919 the authors have been training midwives at a maternity training school in connexion with the Church Missionary Society's hospital at Namirembe, Uganda. Last year the Government of Uganda established a Central Midwives Board and a diploma in midwifery for the Protectorate. It is for these pupil midwives that this book is intended—to be supplemented, of course, by much oral and practical training. To judge from the chapter headings and illustrations it follows the accepted lines of the simpler textbooks in this country. It has been drawn up by the authors in faith and hope, and in the same spirit we congratulate them upon it and wish for it a very fruitful career. The excellence of its format is highly creditable to the Society, which has thus added one more to the large series of educational works in African languages with which it has enriched literature.

### NOTES ON BOOKS.

THE eighth volume of *Medical Science: Abstracts and Reviews*, published for the Medical Research Council by the Oxford University Press, was completed in the issue for September, and an index is published in the first (October) number of the ninth volume. A feature of the periodical is that each number contains one or more reviews on some particular subject and that these reviews are accompanied by bibliographies. One of the reviews in the first issue of the ninth volume is by Dr. F. M. R. Walshe; in it is summarized the work of Magnus and his collaborators on the pharmacology of the nervous system, with special reference to postural and other reflex reactions. Through the work of Sherrington and Magnus it is now possible to form a fairly precise estimate of the origin and nature of many of the motor disturbances in hemiplegia and paraplegia, whereas we are still completely in the dark as to the meaning of the various components of the so-called "corpus striatum syndromes." The pharmacology of the nervous system must be resurveyed in the light of recent advances. Dr. Walshe's review consists of a brief discussion of papers recently published by Magnus and his school; they are the first applications of the physiological investigations carried out at Utrecht during the past ten years. They give an earnest of further advance in the knowledge of various disorders of function in the nervous system built upon the same foundation.

Dr. HENRI MALLIÉ'S little book on paratyphoid and Gaertner infections\* is divided into four parts. The first consists of an historical and bacteriological account of paratyphoid bacilli, though here and throughout the book we miss any reference to *B. paratyphosus* C; the second part is devoted to etiology, morbid anatomy, and complications of the first part deals with the symptoms and gastro-enteric forms of paratyphoid fevers, the typhoid and gastro-enteric forms being discussed successively; and the fourth part is concerned with diagnosis and treatment. Useful statistics are given relating to paratyphoid carriers (p. 38), the incidence and mortality of paratyphoid fevers A and B (pp. 118-122), and the frequency of various complications, especially intestinal haemorrhage (p. 85). Special interest attaches to the prophylactic and curative administration of vaccine, which has been successfully employed in France. The book contains a clear exposition of the subject, being written, as Professor Carles says in the preface, by a practitioner for practitioners, for whom, owing to the prevalence of paratyphoid fevers in France since the war, such a work will be specially useful.

The fourth edition of the *Handbook of Tuberculosis Schemes*† is similar to the previous edition on which we commented last year. For those who have not had the good fortune to encounter this book we may say that its general purpose is to supply information relating to the measures which are in use throughout Great Britain and Ireland for the control of tuberculosis. Summarized under county and county

borough headings are preliminary data on the area, population, and industries of the district concerned, together with the death rate from all causes, and from pulmonary and non-pulmonary tuberculosis in the year 1922. Then follow details of the tuberculosis dispensaries, sanatoriums, hospitals, farm colonies, and open-air schools, and of the medical staff and care committees operating under the scheme. Admirable alike in arrangement and completeness, it should be found invaluable for all those engaged in the treatment of tuberculosis. We congratulate the National Association on this fresh product of its activity.

### PREPARATIONS AND APPLIANCES.

#### *Emetine Periodide.*

EMETINE PERIODIDE ( $C_{21}H_{29}N_3O_6$ , 61) is a preparation introduced by the firm of W. Martindale as a substitute for emetine bismuth iodide. This latter drug was prepared to enable emetine to be given by mouth in amoebic dysentery without producing vomiting. It was believed that it was insoluble in weak acids and would pass through the stomach without dissolving, but would be split and brought into solution in the alkaline contents of the intestine. Unfortunately emetine bismuth iodide slowly dissolves in 0.2 per cent. hydrochloric acid, and hence may exert an emetic action unless further protected by a salol capsule. The disadvantage of the latter procedure is that salol capsules are liable to escape solution in the gut and to be excreted unchanged. The preparation emetine periodide contains 38.7 per cent. emetine base. Its production appears to be a distinct advance on "emetine bismuth iodide," as it is almost completely insoluble in weak acids but is dissolved and split up by weak alkalis. Its chemical properties have been described by W. H. Martindale, and as a result of extensive clinical tests on refractory cases of amoebic dysentery Dr. J. G. Willmore‡ concluded that it was "by far the most effective and at the same time the least toxic of all the emetine preparations which I have tried."

#### *Scillaren.*

Many vegetable drugs of established utility have not hitherto been brought under exact pharmaceutical control. Among these there are few of greater interest than squill. The potency of the active constituent and its minute and varying proportion have been causes of an uncertainty of action which militated against its adoption as long as only galeical products of the drug were available. A glucoside from squill is now being manufactured by the Sandoz Chemical Company which is claimed to be a product of definite identity. The article is sold under the name of "Scillaren Sandoz," and is supplied in the form of a solution and tablets for internal administration and also in ampoules for intramuscular or intravenous injection. Samples submitted to our analyst are reported by him to contain proportions of the glucoside which are too minute for a chemical estimate to be made of its individual quality, but his examination has enabled him to observe that the active principle has been so well purified as to admit of standardization of the preparations. It will be a cause of satisfaction to know that preparations of squill of standard activity are obtainable.

#### *A Dissecting Microscope.*

Messrs. R. and J. Beck (68, Cornhill, E.C.3) have recently introduced a new form of microscope for dissecting, which is much more handy than the old-fashioned wooden apparatus. Its main advantage, however, is in the absolute stability of the two hand-rests—a point of essential importance lacking in the apparatus commonly in use which follows the design of ordinary microscopes as regards the base and stage. In the Crescent Dissecting Microscope, the general character of which can be gathered from the accompanying drawing, the main casting is very wide and supports the hand-rests, so that there is no tendency to tip the instrument. The apparatus is provided with a large glass stage, and can be used with a single lens or, if required, the tube of a single or binocular microscope is readily inserted.

which can be gathered from the accompanying drawing, the main casting is very wide and supports the hand-rests, so that there is no tendency to tip the instrument. The apparatus is provided with a large glass stage, and can be used with a single lens or, if required, the tube of a single or binocular microscope is readily inserted.

 § J. G. Willmore, *Ibid.*, p. 13.

Committee's reply to the Minister says, "it is only too plain, are concerned much more with the building up of surpluses than with the building up of a satisfactory National Health Insurance scheme which shall be preventive as well as curative."

The position and powers of approved societies in the insurance scheme were set out in general terms in our leading article last week. Through the efforts of the profession and by the deliberate judgment of Parliament they were excluded as such from the administration of medical benefit, but they are entrusted with great powers in respect to cash payments during incapacitating sickness and disability, and with regard to certain "additional benefits." Ever since the first publication the more successful societies, by unforeseen Acts and by uniting to establish a quasi-charitable society to do for them what they are unable legally to do for themselves, have attempted to exploit and control the services of hospital staffs and of consultants and specialists. Insidiously but constantly efforts are being made to extend and intensify this control. By the intricacies of insurance finance and by the technical crediting to them as a matter of book-keeping of sums of money contributed jointly by employed persons, employers, and taxpayers, approved societies are now claiming that they have a deciding voice as to the terms and conditions of service of insurance practitioners, and are explicitly denying the right of the Minister of Health to apply any portion of the National Health Insurance Fund to remuneration for these services beyond what they are themselves pleased to consider proper. It is to be hoped that there are some wiser officials of approved societies who view these developments at least with disquietude; but recent speeches and letters and statements by presumably responsible leaders of approved societies make it clear that their aim is to become the dominating factor in the insurance scheme and more and more completely the masters of the doctors. Approved societies have their proper place in the scheme, but it is not the place they are attempting to usurp.

This, therefore, is a matter affecting not only insurance practitioners, or merely such consulting physicians and surgeons, pathologists, and radiographers as may be rendering service in connection with the additional benefits provided by some societies; the honour and interests of the whole profession are deeply involved in it. It is clear that all the efforts of the Insurance Acts Committee, prolonged and sincere as they have been, towards conciliation and the cultivation of a friendly spirit, have had not the slightest effect upon approved society leaders. Indeed an ostentatious lack of appreciation of these efforts, repudiation of previously accepted conclusions, misrepresentations of medical opinion, and a very regrettable disregard of truth, have increasingly become characteristic of their attitude. Boasters of the importance of the profession and of what the societies will be able to do in the direction of a cheap medical service when they have established their power have become louder and more confident. It is an imperative necessity for the profession to put an end to this. The issue has now become at once more critical and more simple. Freedom from friendly society control was perhaps the most "cardinal" of the 1911-12 points. This freedom is now once more seriously jeopardized. The profession must now decide once and for all whether it will submit to approved society domination or whether it will take the lowest figure, and who, as the Insurance Acts

ing's characterization of his own times. Professor question is almost as optimistic as Professor those who have been touched by the spirit will magical without buying or selling an adwoson, to be ble, and the temptation perhaps grows, to be

## ALL THE APPROVED SOCIETIES RULE THE PROFESSION?

THE PROFESSION? The leading article published last week (p. 669) drew attention to the wide extent and the great abilities of the service, and to the persistent efforts have been made on behalf of the profession by the Finance Acts Committee to improve it by suggesting accepting new arrangements to meet every legitimate criticism and by trying to cultivate a spirit of co-operation with all classes of officers and administrators who are concerned in its working. We need the dangers, both to the national health and to the whole medical profession, of a rate of remuneration which would narrow the outlook and stunt the developing usefulness of the service, and would and dishearten large numbers of practitioners whose inclusion within it the real value of the Minister of Health to take this wider view and make some further proposals which would secure full help of a contented profession.

is a matter for extreme regret that the Minister failed to use his opportunity. The Insurance Committee, confident in the strength of arguments and facts there has been no real attempt to recommend that the matter in its economic aspects should be submitted to arbitration as in 1920. It has been refused—it we understand rightly the paragraph in the Minister's unsatisfactory letter of October 15th. The result of any such arbitration would have been loyal acceptance of this time, as last way to a peaceful solution seems to have been the course of events since the Minister made his statement, made it evident that the purely economic element, important as it is, has become of lesser importance, and that the plain and clear issue now is not a national service, to dictate to Ministers, and the profession will be fighting not only its own battle but of the community at large. The question which whether the public health and national aspects of the profession and the Government alike have to face insurance system are to be sacrificed to the interest and power and selfish advantage of a mere section, approved society officials, whose object, very little advised, is to buy the medical profession outright at lowest figure, and who, as the Insurance Acts

The following is the reply of the Insurance Acts Committee to the Minister's letter of October 15th printed above:

British Medical Association,  
Medical Department,  
429, Strand, W.C.2.

Sir,

I beg to acknowledge receipt of your letter of the 15th October. The Committee understands:

(1) That the Minister is unable to accept the suggestion that arbitration offers a method of arriving at a peaceful arrangement.

(2) That he is unwilling to allow any further negotiations until he has been convinced by some other method that it is impossible for him to obtain a satisfactory service under his present offer.

The Committee would have preferred the method either of arbitration or of negotiation, but has no option but to accept the responsibility he now imposes on it.

The Committee's position is—

(1) That on the purely economic question, on which it is still prepared to negotiate, the remuneration the Minister suggests is insufficient, and that there has so far been no real answer to the facts and conclusions set out in the Committee's first Memorandum (M.1) and the accompanying statement by Professor Bowley.

(2) That no national medical service based on an insurance system can be satisfactory unless it attracts all types of general practitioners in sufficient numbers and so supplies the industrial population, whether in town or country, with that choice of doctor and satisfactory service which obtains among other classes of the population.

(3) That while willing to serve the community to the best of its ability and to make any satisfactory arrangement to this end with the representatives of the community, the profession is not prepared to accept the position of being under the dominance or control of a particular section.

(4) That arrangements consistent with these principles can be agreed to by the Committee and would not, in its opinion, involve any further contribution from the taxpayer or any diminution of the benefits to which insured persons are entitled.

I am, Sir, your obedient servant,

ALFRED COX,

Medical Secretary.

October 15th, 1923.

### THE INSURANCE CRISIS: THE MAIN ISSUE.

What practitioners should clearly understand is that the present conflict is not mainly upon the inadequacy of the capitation fee offered, but upon the old question, fought successfully in 1911 and 1912, of whether the profession shall be free from Friendly Society control. A discussion of the present situation will be found in a leading article at page 725 of the "Journal." Other reports, notes, and correspondence relating to the insurance crisis appear in later pages of this "Supplement." We hope to publish next week a full report of the Panel Conference which is being held in London as we go to press.

### British Medical Association.

#### CURRENT NOTES.

##### The Council Dinner.

IN an annotation on page 673 of the JOURNAL of October 13th reference was made to the second annual Council dinner, which is to be held at the Hotel Victoria, Northumberland Avenue, at 7 for 7.30 p.m. on October 24th. Members of the Association are reminded that they should make early application for tickets, particularly if they are bringing guests, who may be ladies or gentlemen. The list of guests who have accepted the Council's invitation is a distinguished one. It includes the Minister of Health, the President of the Royal College of Physicians of London, the President of the Royal College of Surgeons of England, the President of the Royal Society of Medicine, Lord Justice Atkin, Sir George Newman, Sir Arthur Robinson, the Registrar-General, the heads of the Medical Departments of the Services and the Medical Adviser to the India Office, the President of the Society of Medical Officers of Health, the President of the Association of County Medical Officers of Health, the President of the Medical Women's Federation, the Vice-President of the Royal College of Veterinary Surgeons, the President of the British Dental Association, the Registrar of the General Medical Council, Sir Philip Magnus, Sir Henry Craik, and the following medical members of Parliament: Sir S. Russell-Wells, Sir John Collie, Major L. G. S. Molloy, and Dr. Thomas Watts.

The chief guest of the evening will be Sir Dawson Williams on the occasion of his completion of twenty-five years as Editor of the BRITISH MEDICAL JOURNAL, and many old contributors have announced their intention of being

present. Applications for the remaining tickets should be made at once to Mr. L. Ferris-Scott, Financial Secretary, 429, Strand, W.C.2. The price is 10s. 6d., exclusive of wine.

##### Correspondence regarding the Insurance Crisis.

The Medical Secretary desires to thank many correspondents who have written giving either their own ideas or what they have gathered as to the views of the profession in their areas. He finds the information most useful and cheering, but hopes that those to whom he does not send a personal reply will understand that the pressure of work just now renders it impossible to make individual replies to all.

##### Labour Party and the Capitation Fee.

The lay press during this week has been commenting on a report issued by the General Council of the Trades Union Congress and the Labour Party National Executive on medical benefit. It is very interesting to note that this important political body agrees that, if the services are improved in accordance with the arrangements already made between the Insurance Acts Committee and the Ministry, the service "would be such as to justify a capitation fee to the doctors of substantially the present amount without ruling out of present consideration any claim by the medical profession for something beyond this, and we have satisfied ourselves . . . that the National Health Insurance Fund in the aggregate contains sufficient money to meet the cost without lowering or endangering the revision of the other benefits (whether normal or additional) to which insured persons are entitled." This is a complete vindication of the British Medical Association's claim, and it now remains for the Labour Members of Parliament to translate into action the opinion thus expressed by the two important bodies of which they are members.

14. In any schemes for providing hospital benefit by voluntary hospitals, it is undesirable that the hospitals concerned should undertake any insurance risk, i.e., undertake to provide hospital benefit, when required, in return for a periodic payment by an individual or a group of individuals; so that where schemes are set up to provide payment for hospital benefit for specified individuals or groups of individuals, such schemes should be organized not by the hospital, but by some independent body.

15. The acceptance by voluntary hospitals of an insurance risk under any scheme for the provision of hospital benefits would (a) prejudice the primary consideration in the admission of a patient to hospital, namely, the suitability of the case for admission on medical grounds; and (b) in the event of the actuarial estimates upon which the scale of premiums and benefits are based proving faulty, render the hospitals liable to meet outlays for which there was no financial provision, and consequently endanger the purely charitable funds of the hospitals.

16. In any contributory scheme the presence, limitations, or absence of a contractual obligation for the provision of hospital and additional benefits should be plainly stated to the contributors. Failure to provide such statement is likely to reflect upon the good faith of the hospitals and of the promoters of the scheme.

#### V.—SUITABILITY OF PATIENTS FOR HOSPITAL TREATMENT.

17. The primary consideration in the admission of a patient to hospital should be the suitability of the case on medical grounds.

18. Some means of investigation into the circumstances of the applicants for relief, by means of an almoner or other agent, should be employed in all medical charities.

#### VI.—CATEGORIES OF PATIENTS FOR IN-PATIENT TREATMENT.

19. Patients admitted to voluntary hospitals should be classed under the following groups: "Free" (Indigent), "Tariff," and "Private":

- (a) *Free (Indigent) Patients.* Those certified by the almoner or other officer of the hospital as unable to contribute in any way towards their maintenance and treatment;
- (b) *Tariff Patients.* Those paying, or for whom is paid, in part or in whole, the tariff cost of maintenance and treatment; this group includes all those for whom any payment has been made by (i) public authorities; (ii) approved societies, employers of labour, insurance companies, or other bodies; or (iii) under any contributory scheme; and
- (c) *Private Patients.* Those who pay for special accommodation and who arrange for medical treatment fees independently of the hospital.

(NOTE.—The Council has been instructed by the A.R.M., 1923 (Min. 83), to consider a suggestion that foregoing paras. (a) and (b) be amended.)

#### VII.—FREE (INDIGENT) IN-PATIENTS.

20. Those certified by the almoner or other officer of the hospital as unable to contribute in any way towards their maintenance and medical treatment; and for whom hospital benefit is provided by the gratuitous contributions placed at the discretion of the hospital managers and by the gratuitous services of the honorary medical staffs.

21. Cases of obvious destitution or cases already in receipt of poor law relief should, after they have been seen once in the casualty or out-patient department, be referred to the poor law relieving officer, unless they should be retained by the hospital for treatment. But in case of patients referred by poor law medical officers to hospital for consultation or treatment, payment should be required from the poor law guardians both for advice, treatment, and maintenance.

#### VIII.—TARIFF IN-PATIENTS.

22. When the board of management of a voluntary hospital enters into a financial arrangement with an employer of labour, a public authority, approved society, insurance company or any other body, or under a contributory scheme for the reception of patients, such arrangements should be taken to cover the full cost of maintenance and medical treatment, and should provide as follows:

- (a) Payments made for Tariff In-Patients should be for work done based upon a tariff of fees agreed upon from time to time between the contracting parties; such tariff of fees making full allowance for provision of hospital accommodation, maintenance, and payment of medical staff.
- (b) The accounts of the hospitals should be kept so as to show the cost of this hospital benefit.
- (c) Inability to pay for adequate treatment as a private patient whether in the hospital or outside, should be the consideration for the admission of all tariff patients for hospital treatment.
- (d) All persons, whether insured under the National Health Insurance Acts or not, whose income from all sources does not exceed the limit of a specified scale, should be eligible for hospital benefit on tariff rates. The hospital should reserve its right to challenge admissions.

(The following maximum scale is suggested, subject to economic and local variations and to periodic revision:)

#### CLASS 1.—Limit of Income £200.

- (a) Single persons over 16 years of age.
- (b) Widow or widower without children under 16 years of age.

#### CLASS 2.—Limit of Income £250.

- (a) Married couples without children under 16 years of age.
- (b) Persons with one dependant under 16 years of age.

#### CLASS 3.—Limit of Income £300.

- (a) Married couples with a child or children under 16 years of age.
- (b) Persons with more than one dependant under 16 years of age.)

(c) For those persons whose income places them beyond the agreed specified scale for tariff patients, arrangements may be made to receive them as private patients, for the conditions governing which see Sections IX (a) and IX (b) below.

(f) The ordinary hospital routine of admission, transference, and discharge of patients should not be modified for tariff patients, nor should any preferential treatment be given to them.

(g) No tariff patient should be admitted without the recommendation of the attending practitioner, except in the case of emergency.

#### IX (a).—PRIVATE PATIENTS IN NURSING HOMES ATTACHED TO HOSPITALS.

23. Where it is desirable that special accommodation in the nature of a nursing home should be provided in connexion with voluntary hospitals for the reception of private patients, there should be provided as follows:

- (a) Private patients should be admitted to such special accommodation only on the recommendation of a private practitioner, except in cases of emergency. In the latter circumstances the patient's own medical attendant should be informed.
- (b) It shall be open to a private patient to select any registered medical practitioner as his attendant.
- (c) The scale of charges for the private patient for maintenance shall be such as fully to cover every cost to the hospital.
- (d) No fixed rate of payment for professional services rendered to such patients should be established; the fees so payable to remain, as at present, a matter of arrangement between patient, family physician and consultant.

#### IX (b).—PRIVATE IN-PATIENTS IN HOSPITALS.

24. Where private patients are admitted under special arrangements into the public wards of a voluntary hospital:

- (a) Private patients should be admitted to such wards only on the recommendation of a private practitioner except in cases of emergency.
- (b) The scale of charges for the private patient for maintenance shall be such as fully to cover every cost to the hospital.
- (c) No fixed rate of payment for professional services rendered to such patients should be established; the fees so payable to remain, as at present, a matter of arrangement between patient and the member of the staff of the hospital.
- (d) The accounts of the hospital should be kept so as to show the cost of this hospital benefit.
- (e) The ordinary hospital routine of admission, transference, and discharge of patients should not be modified for these private patients, nor should any preferential treatment be given to them.

#### X.—OUT-PATIENTS.

25. The primary object of the Out-Patient Department should be for consultation.

26. Only such treatment should be given as cannot or is not consistent with the best interests of the patients be properly undertaken by a general practitioner of ordinary profession and competence and skill.

27. All cases not suitable for hospital treatment should be referred in general terms to a medical practitioner, to a public medical service, an approved provident dispensary, or to a relieving officer under the poor law.

28. Where arrangements for consultations or specialist services for tariff patients are made under some contributory scheme or otherwise, such arrangements should provide that these services shall be given so far as is possible and consistent with the best interests of the patients by the private practitioner at his consulting rooms or at the patient's own home and not at the out-patient department of the voluntary hospital.

29. Private patients should not be seen or treated at the out-patient department of a voluntary hospital except where no other arrangement is practicable, or in case of emergency, and in such cases preceding paragraph 23 (c) and (d) should govern arrangements.

30. In cases where consultations or treatment are given at an out-patient department, the ordinary hospital routine should not be modified, nor should any preferential treatment be given to tariff or private patients.

## CARDIAC CLINICS.

The discussion on the etiology and treatment of heart disease in early life in the Section of Medicine at Portsmouth is published at page 702, and the situation is reviewed in a leading article on page 723.

The Association for the Prevention and Relief of Heart Disease in New York, which seeks to promote the establishment of cardiac clinics, has recently forwarded us a copy of a statement of what it regards as the minimum requirements for cardiac clinics. Every cardiac clinic, it is considered, should have more or less direct connexion with a ward service, should work in co-operation with agencies providing convalescent and country care, and with social service work in the district from which it draws its patients. Further, it is thought desirable that a clinic should co-operate with schools, day nurseries, and the like in its district, and furnish reports on the diagnosis and treatment of the children coming under its care. The hospital wards would be available for the initial study of each case and for the treatment of those patients unable or too ill to receive proper care at home; the cardiac clinic would also treat patients after they left the wards. The following is the text of the statement on the minimum requirements:

## MINIMUM REQUIREMENTS FOR CARDIAC CLINICS (New York).

**I. Medical Organization.** The chief of clinic must be a physician of sufficient experience with patients having heart disease to meet the approval of the Executive Committee of the Association. Staff: There must be at least one physician for every fifty active patients enrolled in the clinic.

**Ward Facilities:** There must be at least an affiliation with a ward service where cardiac cases may be admitted.

**II. Social Service.**

There shall be at least one social service worker connected with the clinic.

**III. Space Equipment and Facilities.**

1. There shall be at least one waiting-room and separate rooms for the examination of men and women patients in adult clinics.

2. There shall be an examining table in each room, at least one pair of scales, and a sphygmomanometer in the clinic.

**IV. Records.**

Records of patients, history, physical examination, treatment, and follow-up notes, including social service activities, must be kept in a manner meeting the approval of the Association. These must be filed in such a way as to be easy of access.

**V. Admission and Distribution of Patients.**

Only patients having potential or organic heart disease shall be enrolled. No patient shall be carried on the active list of a clinic who has not reported in the month.

**VI. Standards for Physical Examination.**

A. Each patient should have a complete physical examination on admission and receive such examination as is necessary on subsequent visits.

B. All doubtful or unusual cases should be seen by the chief of clinic or consulting physician.

**VII. Standard for Treatment.**

A. Relation to Public School System.—The clinic should co-operate with the schools, social agencies, and day nurseries, etc., by the diagnosis and treatment of referred cases. It is desirable that cases should be referred only from a specified district, usually agreed upon, and that, so far as possible, cases should be referred by appointment in such numbers and at such hours as may be of greatest mutual benefit.

B. Convalescent or Country Care.—Close co-operation should be maintained with the agencies providing convalescent and country care.

C. Consultation Facilities.—There should be facilities for consultation in all required specialties.

D. Amount of Medicine.—The amount of medicine dispensed should be sufficient to obviate the return of patients for medicine only.

E. Purposes of classification patients attending the clinics are divided into three main groups:

**1. Organic heart disease.**

2. Patients with abnormal signs or symptoms, not believed to be due to organic disease.

3. Potential disease—patients without circulatory disease but who are kept under observation because of the presence or history of an etiological factor.

For the complete diagnosis of organic cases, the disease has to be classified under four different titles, according to

the value of improved sanitation is admitted, its limitations, regarded as a preventive agency, are clearly brought out. The safety of properly conducted vaccination is made manifest. A note on the working of the Vaccination Acts is included, and a hitherto unpublished incident of Sir H. M. Stanley's last expedition to Central Africa, which has a considerable evidential value, is related. This address is of especial value at the present time, when a simple but effective statement is required of the solid basis of fact on which the case for vaccination rests; the fanciful assertions of the antivaccination propaganda can be combated decisively with its aid. The Research Defence Society has again merited the gratitude of the medical profession generally for a timely and valuable publication which should be widely circulated. Its simplicity of language and clearness of argument enable it to be understood and appreciated by the average layman, whom it should interest and convince. The medical practitioner will also find in it some valuable weapons against the opposition of the antivaccination partisans. Its brevity and excellent paraphrasing will enable him to assimilate rapidly the considerable amount of evidence which is comprised in it. We are glad to be able to state that its author has consented to revise the British Medical Association's pamphlet *Small-pox and Vaccination*, which has been for some time out of print.

## INTERNATIONAL CLINIC OF PLASTIC SURGERY.

A gap in the practice and teaching of plastic surgery is to be filled by the establishment of an international clinic in association with St. Andrew's Hospital, Dollis Hill, London, N. A portion of the existing building will be used until funds are available to build another wing to the hospital devoted entirely to the reception of cases requiring plastic operations. The clinic vindicates the word "international" in its title by the constitution of its staff, which consists of Mr. H. D. Gillies and Mr. T. Komtser Kliner (Great Britain), Dr. J. Eastman Sheehan (France), and Dr. Ferris N. Smith (America), and Professor Lemaître (France). This, it is hoped, will ensure that a knowledge of the best methods of foreign specialists will be made generally available to British and foreign surgeons, for whom post-graduate courses will be arranged. It is estimated that a sum of about £25,000 in all will be required. Donations, made payable to "The International Clinic of Plastic Surgery," will be received by the London Joint City and Midland Bank, 69, Pall Mall, London, S.W.1. Accommodation will be provided for both paying and free patients; the latter will be charged only the cost of their maintenance while in hospital.

A further announcement regarding the Council Dinner of the British Medical Association, on Wednesday next, October 24th, appears in the SUPPLEMENT at page 174. Members of the Association wishing to attend should apply at once for tickets (price 10s. 6d. each, exclusive of wine) to the Financial Secretary, 429, Strand, W.C.2.

The Honorary Fellowship of the American College of Surgeons is to be conferred upon Sir William Wheeler, President of the Royal College of Surgeons in Ireland, at the convocation ceremony in Chicago on October 26th. Sir William Wheeler left for America last week, having accepted an invitation of the Regents of the American College of Surgeons to deliver the Fellowship Address on this occasion.

Owing to the great pressure on our space, due to the insurance crisis, the Epitome of Current Medical Literature is held over this week.

III. The Conference is in general agreement with the view of the Consultative Council on Medical and Allied Services as stated in that part of paragraph 6 of its interim report, which recited :  
" Preventive and curative medicine cannot be separated on any sound principle, and in any scheme of medical services must be brought together in close co-ordination. They must likewise be brought within the sphere of the general practitioner, whose duties should embrace the work of communal as well as individual medicine."

IV. The Conference is therefore prepared to advise Local Authorities :

- (1) That where private general practitioners place their opinions before local authorities on any proposed scheme of medical survey or inspection and treatment, their representations should have due consideration by the Local Authority in order that it may be ascertained how far it is practicable or desirable to give effect to their view.
- (2) That those engaged in general practice must either be prepared to accept responsibility for the treatment of such of their private patients as are discovered by medical survey or otherwise by the Local Authority to be in need of treatment, or they should agree that treatment be undertaken by the Local Authority without regarding such medical provision as an encroachment on their practice. To this end persons found to be in need of treatment should, in the first instance, be referred to their private medical practitioner, or if they have no regular medical attendant they should be advised to consult a private medical practitioner.
- (3) Private practitioners should assist Local Authorities by intimating their willingness or otherwise to undertake the treatment of patients discovered in the manner stated to be in need of treatment.

V. That practitioners, and by arrangement medical students, should have access to centres and clinics established by Local Authorities, in order that they may gain such experience as the centres and clinics afford.

VI. That private medical practitioners should be able to refer to clinics and centres for advice and treatment patients who would thus be most appropriately provided for.

VII. That payments or charges, if any, made in respect of medical treatment should be either voluntary or of such a character as will not deter persons from seeking advice and obtaining early treatment.

VIII. Centres and clinics should be established and administered for the benefit of—

- a) Those who are unable, for some reason, to obtain treatment from a private doctor, and
  - b) Those who, as a result of supervisory medical work undertaken by the Local Authority, are discovered to be ill, and for whose ailments treatment would not be sought unless it were provided by the Local Authority.
- treatment at centres and clinics should be such as can actually given therein, and should not include any treatment that makes domiciliary attendance advisable or involves any of more than forty-eight hours at any clinic where beds provided.

X. The Conference is of opinion that in the interests of harmonious working and the acquirement of clinical experience possibility should always be considered of clinical work for the Public Health Authority being carried out through the agency of private practitioners where conditions are suitable.

X. For the purpose of a better understanding, the Conference desires to state further :

- (1) That private general practitioners or consultants accepting offices under local authorities must realize that the duties of these offices require to be fulfilled strictly in accordance with the conditions of the appointments and in priority of all other engagements.
- (2) That health policy is settled by Local Health Authorities, not only on medical grounds but after due regard has been given to the closely related questions of administration and finance, local conditions, and other relevant considerations.
- (3) That the medical officer of health should so far as possible secure the co-operation of the local medical profession in the discharge of his duties.
- 4) That the final decision on health policy must always be with the Local and Central Authorities.
- 5) That it is the duty of the medical officer of health to ensure that effect is given to the decisions of those authorities.

# SCALE OF MINIMUM COMMENCING SALARIES FOR WHOLE-TIME PUBLIC HEALTH MEDICAL OFFICERS.

As approved by Annual Representative Meeting, 1923.

|                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |                                                                                                                                                 | *Minimum Commencing Salaries per annum.                                                                                                                               |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| RESIDENT MEDICAL OFFICERS                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |                                                                                                                                                 | £150 plus emoluments                                                                                                                                                  |
| DEFINITION.—These are Medical Officers employed in Hospitals, Sanatoria, or other Institutions without responsibility for the work of other Medical Officers.                                                                                                                                                                                                                                                                                                                                                                                                  |                                                                                                                                                 |                                                                                                                                                                       |
| NOTE.—Where the appointing authority limits the appointment to a term not exceeding one year and not renewable, this salary shall not apply.                                                                                                                                                                                                                                                                                                                                                                                                                   |                                                                                                                                                 |                                                                                                                                                                       |
| MEDICAL OFFICERS EMPLOYED IN DEPARTMENTS.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      | Working directly under a Senior Medical Officer.                                                                                                | £60                                                                                                                                                                   |
| DEFINITION.—These are Medical Officers without responsibility for the work of other Medical Officers but who shall have had at least three years' experience in the practice of their profession subsequent to obtaining a registrable qualification.                                                                                                                                                                                                                                                                                                          |                                                                                                                                                 |                                                                                                                                                                       |
| SENIOR MEDICAL OFFICERS IN CHARGE OF DEPARTMENTS—for example, Port Sanitation, School Medical Departments, Tuberculosis Departments, Mental Deficiency Departments, Maternity and Child Welfare Departments, Venereal Disease Departments, or any other similar departments, or combination of departments, and Medical Superintendents of Hospitals, Sanatoria, or other Institutions.                                                                                                                                                                        |                                                                                                                                                 | Without Assistants<br>With 1 Assistant<br>2<br>3<br>4<br>5-6<br>and for every completed two or less                                                                   |
| DEFINITION.—These are Medical Officers who are in charge of departments and are directly responsible to the Medical Officer of Health or otherwise.                                                                                                                                                                                                                                                                                                                                                                                                            |                                                                                                                                                 | £7.0<br>£900<br>£950<br>£1,000<br>£1,050<br>£1,100<br>an additional £50                                                                                               |
| DEPUTY, OR CHIEF ASSISTANT, MEDICAL OFFICERS (Hospitals, Sanatoria, or other Institutions and Departments).                                                                                                                                                                                                                                                                                                                                                                                                                                                    |                                                                                                                                                 | A salary equal to 60 per cent. of the salary of the Medical Superintendent or Senior M.O. in charge, but not less than the salary of a M.O. employed in a department. |
| DEPUTY OR ASSISTANT MEDICAL OFFICERS OF HEALTH.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |                                                                                                                                                 | A salary equal to 60 per cent. of the salary of the M.O.H., but not less than the salary of the next grade of medical officer in the department.                      |
| DEFINITION.—A Deputy or Assistant Medical Officer of Health is a medical officer duly appointed as deputy or assistant medical officer of health by the local authority to assist the Medical Officer of Health in the general administration of the health department and the carrying out of the various Acts, by-laws, orders, rules, regulations, etc., required to be usually administered by the Medical Officer of Health; the title deputy or assistant medical officer of health to be limited to medical officers carrying out these general duties. |                                                                                                                                                 |                                                                                                                                                                       |
| MEDICAL OFFICERS OF HEALTH                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     | Population.                                                                                                                                     |                                                                                                                                                                       |
|                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                | Under 35,000<br>" 50,000<br>" 75,000<br>" 100,000<br>" 150,000<br>" 200,000<br>" 300,000<br>" 400,000<br>" 500,000<br>" 600,000<br>Over 600,000 | £8 0<br>£9 0<br>£10 0<br>£11 0<br>£12 0<br>£13 0<br>£14 0<br>£15 0<br>£16 0<br>£17 0<br>£18 0                                                                         |

NOTES.  
(a) These salaries are not, any expenses necessitated by the duties being provided in addition.  
(b) Population means population at the latest Annual Report of the Registrar General.  
(c) No existing officer should be prejudicially affected by the operation of the scale.  
(d) ANNUAL INCREMENTS should be at the rate of 5 per cent. per annum, rising to 40 per cent. above the minimum basic rates.  
(e) BONUS.—The current Civil Service cost of living bonus should be applied to the foregoing scales.  
(f) The salaries of Medical Superintendents of Poor Law Hospitals should be as for Senior Medical Officers in charge of departments as set out above.

personnel is not less but rather more numerous than in any other (partly) certain that the addition to the number of deaths of doctors from w, Retrograd, and other places are studying and qualifying, and the which is endeavouring to obtain the m. We may therefore anticipate a number of children to be dealt with by bringing order into this service will bring forth the epidemic it has brought the epidemic under- the ly diseased from the normal—and we may be sure that the capacity which has marked the whole Russian attention of the Commissariat of wily parallel with those of England

### NEW WATER SCHEME FOR BELFAST.

ON October 10th Lord Carson cut the first sod of the new water scheme for Belfast. In dry summers the amount has not been sufficient, and the hours of supply have been very seriously limited. The new scheme has been in difficulties and by the war; it will take some seven years to complete, and will cost about a million sterling. An artificial lake will be formed in the Silent Valley in Mourne Mountains, by constructing a huge dam across its mouth. When the undertaking is completed a supply of some thirty million gallons a day of the purest water will be available.

### ROYAL MEDICAL BENEVOLENT FUND SOCIETY OF IRELAND.

The eighty-first annual report of the Royal Medical Benevolent Fund Society of Ireland states that, despite the many general and local difficulties they have had to meet, the honorary secretaries and treasurers in practically all the counties of Ireland have maintained their support and in many cases actually sent in an increased subscription; most thanks are due to those gentlemen who have not only subscribed liberally themselves but have given up their time to further the interests of the Society, and so to help their colleagues who have met with misfortune, and the widows and orphans of those who have passed away.

tion to the early knowledge of neurology, and his doctrines of sympathetic action had successfully replaced the aut- mistic doctrines of Stahl and the theories of von Haller by von Baer, von Kölliker, and others, had had a very important influence in elucidating the development, and thus indirectly in the functions, of the nervous system. Bichat, at the end of the eighteenth century had taught that the voluntary and sympathetic systems were completely independent, an advance in its time but now shown to be untenable in its entirety. The theories of Gall and Spurzheim had at least the advantage of drawing attention to the question of localization of function in degeneration of the nervous system. The first great step in differentiation of function of different parts was the discovery by Charles Bell in 1811 that the anterior spinal roots were motor and the partial discovery of the functions of the posterior roots, which was followed eleven years later by the complete demonstration of their functions by Magendie. To Gaskell physiology owed the greater part of the knowledge regarding the paths of voluntary and involuntary impulses respectively through the spinal cord, though the ramus communicans had been discovered by Haller. It was a curious point that the degeneration of the motor tracts in the medulla which had been well known to the ancients and described by Aretaeus in the first century had been forgotten and had to be rediscovered in the nineteenth century. The discovery of reflex action by Marshall Hall in 1822 was a most important advance. The name of Flournoy was still associated with the localization of the breathing centre (1837), to which he gave the name *nervus vitalis*, successive steps in further localization had been made by Schiff, Fritsch, Hitzig, Ferrier, and others. In clinical neurology one of the earliest names to be remembered was that of Rod, who described the connection of the symptoms with the pathological changes in locomotor ataxia, as this disease was later named by Duchenne. The name of Charcot was specially connected with the discovery and description of disseminated sclerosis and with the elucidation of various functional conditions. Finally, the brilliant results which had been attained towards the latter part of the century by neurologists were bound up with the name of Horsley more than any other.

the bacteriology of aerated waters, which was discussed by Dr. Lucian de Zilwa, Dr. A. Nell, and the president. Dr. Lucian de Zilwa showed cases of (1) pseudo-hypertrophic paralysis; (2) hysterical stocking anaesthesia; and read notes on (1) a case of uterine fibroids, and (2) a case of advanced ectopic gestation. The cases were discussed by Dr. H. M. Peries. Lastly, a meeting of the Branch was held on June 13th, with Dr. M. Rustomjee, vice-president, in the chair, when the honorary secretary read a paper by Dr. E. Garvin Mack on acute diabetes mellitus, which was discussed by Dr. W. Lionel de Silva. The honorary secretary also read a paper by Dr. S. Ramanathan on the relationship of herpes zoster to chicken-pox, which was discussed by Dr. W. Lionel de Silva.

YORKSHIRE BRANCH: BARNSELY DIVISION.

A MEETING of the Barnsley Division was held at the Queen's Hotel, Barnsley, on the evening of October 11th, when the terms of panel service for 1924 were fully discussed. It was unanimously resolved: That this Division strongly supports the Insurance Acts Committee in any action which it may think fit to take.

Dr. T. E. FRANCIS read a paper on the "Present Position of Vaccination," and an interesting discussion followed in which many of the members present took part.

SURREY BRANCH: GUILDFORD DIVISION.

THE first meeting of the winter session was held on October 4th at the Royal Surrey County Hospital, Guildford, when Sir HENRY GAUVAIN delivered a most instructive and interesting address on "The Conservative Treatment of Tuberculous Disease of the Hip and Spine" before an audience of thirty members and four guests. The address was illustrated by a large number of lantern slides which showed the lecturer's methods of treatment and the results obtained therefrom. Sir Henry Gauvain showed various forms of non-inflammable celluloid splints used for ambulatory cases and drew attention to the benefit derived from treatment by direct sunlight, and to the value of the Convalescent Hospital at Hayling Island, where convalescent cases were treated by sea bathing, spraying with sea water, and graduated exercise in the open air. He insisted upon the necessity of having a reliable test in deciding when it was safe to allow a convalescent case to take active exercise. Statistics of the Alton Hospital showed the average stay in hospital was from eighteen months to two years, and that deaths from all causes were between 2 and 3 per cent. In his opinion the rectus abdominis muscles, if this was absent it was safe to take the only test that was of any value was the "referred reflex" of the hip to discard splints and take active exercise. In the discussion regard the disease as quiescent and to allow the patient to take active exercise. Statistics of the Alton Hospital showed the average stay in hospital was from eighteen months to two years, and that deaths from all causes were between 2 and 3 per cent. In the discussion cases followed Drs. THORNE, THORNE, HOPE WALKER, LYNDON, WEAVER, and DUNDON took part.

After the meeting a very successful Division dinner was held at the Angel Hotel, Guildford, when 29 members entertained the following guests: The Bishop of Guildford, the Mayor of Guildford, Sir Henry Buckingham (M.P. for the Chairman and Honorary Division), Sir Henry Gauvain, and the Hospital, Mr. Ferdinand Treasurer of the Royal Surrey County G.C.I.E. The Division Smallpox and General Sir Edmund Elles, G.C.I.E. The Division the opportunity of thanking the Board of Management of the Surrey County Hospital for allowing the Division meetings to be held in the board room of the hospital. The Ulster Cup, was won by Dr. Jobson (a member of the Division) at the competition at the Annual Meeting, Portsmouth, with a score of 100 per cent. The Division was placed on the table and by the kindness of Dr. Jobson was "christened" by the company. During the evening songs were contributed by Drs. Fleming and Jenner.

MEDICAL ORGANIZATION IN SOUTH AFRICA.

OUR contemporary the South African Medical Record, a journal devoted to the interests of the medical profession in South Africa, in its issue for September 8th, 1923, published the following leading article, which we venture to reproduce in extenso:

A Step in the Direction of Unity.

Those who follow the proceedings of the British Medical Association in England, and we hope there are some, especially at the present time, when reports are coming to hand of the Portsmouth Annual Meeting, presided over by a confrere who is a South African by birth and education, can hardly fail to be struck with the extraordinarily high level of organization which the Association has attained, especially in that part of its work which deals with the legitimate material interests of the medical profession.

The point to which we desire to specially direct the attention of our readers is the proved fallacy of the contention which has been made so much of in connexion with the question of establishing a S.A.M.A., or M.A.S.A., in this country, namely, that the constitutional provision forbidding the Association to

become a Trades Union stands in the way of its playing a due part in defending encroachments upon the reasonable rights of its members, a contention upon which the whole case for a new Association was, at the beginning at least, made to rest. Far from this being the case, we have conclusive proof, almost every time that any of us read the *British Medical Journal*, that the position is exactly the reverse, that the attainment of what may be called Trades Union ends is not only a regular aspect of the activities of the Association in Great Britain and Australia, but that those ends are attained in an extraordinarily effective way. We have the story repeated almost week after week of the Association taking up some case, it may be an attempt on the part of a local authority to obtain the services of a medical officer at an unfairly low rate, one of underpayment or interference with the medical Society, one of the part of a public department or what not, status on the part of a medical officer at an Colliery Benefit with the invariable result that, sometimes after a struggle and sometimes almost at once, the Association gains for its members what they desire or something very near it. So marked is this success in the negotiations conducted by the Association that, as most of our readers know, Mr. Sidney Webb, probably the highest authority on Trades Unions and Labour questions in the British Islands, some time ago admitted, almost tearfully, that the British Medical Association, although not a "Trades Union," is far more successful in gaining what may be called "Trades Union ends" than any "Trades Union" in the country. "a weighty utterance indeed, and all the more weighty because it is strictly true. Now, why is it true? We think the Association attains "Trades Union ends" exactly because it is not a Trades Union, because it commands respect from its members and from the Government, the local authorities and the public, for several reasons. One is that it can approach a question by out the mutual hostility and distrust which seem to be the invariable concomitants of any conference between employers and Trades Unions. Another is that, exactly because it is not a Trades Union, it never asks more than it considers fair after ground, and never asks more than it considers fair after survey of both sides of the question. A third is that, unlike Trades Unions, it is a body devoting its attention not only to securing for its members a fair reward for their work, but to bringing it about that that work shall be constantly improving in efficiency. This latter aspect, that of balancing efficient service against reasonable remuneration, is what no Trades Union ever pays any attention to. Trades Unions strive earnestly for better remuneration and easier conditions of labour, but, not only do they severely eschew any attempt to make labour more efficient, but they go further and do all in their power to suppress any individual efforts to increase its efficiency. All people concerned know that a Medical Association keeps in view the giving the *quid* of efficient service for the *quo* of fair remuneration, and they respect it accordingly. And a fourth reason is that a Medical Association, at least a wisely conducted one, relies on moral influence rather than compulsion to bring its own members into line. This last reason we regard of the very highest importance. Medical men are so constituted, and it is well that they are so constituted, considering the nature of their professional work, that there is nothing they hate more than compulsion of any kind, nothing to which they answer more willingly than an expression of corporate opinion which has not force behind it. To use an equine metaphor, "The more you jag their mouths, the more they kick."

Now, our object at present is to commend this moral to our readers at the present juncture, when the fate of organized medical action in this country is trembling in the balance, and when we fear we are face to face with paralysing disunion. We are certain that, with the men who think and whose opinions count in the ranks of the present B.M.A. Branches in South Africa, the most important factor in the persistent opposition of many to the new M.A.S.A. or S.A.M.A. movement is the fear, for which they have much excuse, that the substitution of either of these for the B.M.A. will mean the standard of professional ethics. Cannot some leaders in the new departure make it public that they are prepared to abandon—not merely keep out of sight for the time being—the Trades Union argument, and that they are willing to take their stand merely on the "National" one, which, after all, is far stronger and which secured them far more votes at the Referendum just over. By so doing, they might lose a little support on the East Rand, but we are convinced very little elsewhere, and they would secure in the B.M.A. Referendum a considerable turnover of votes which otherwise will go in the opposite direction. We make this appeal purely in the interests of unity, and quite apart from the merits of one side or the other.

the numbers required to meet the situation; moreover, the Government would be faced with the problem of providing residential and surgery accommodation in each area for the men it introduced. One speaker from the body of the hall criticized the Insurance Acts Committee for not putting "a strong face" to the Ministry of Health!

Dr. A. SALTER, M.P., said that he supported the resolution, though he was bound to make some observations which he feared would be unpopular, and possibly would meet with no agreement in any part of that audience. The first consideration before a policy of resignation was accepted was whether the terms offered were so destructive to self-respect, or the conditions imposed were of such a character, that there was no option but to strike even though certain defeat stared them in the face. He did not believe that the conditions at the present moment were such as called for a strike—that is to say, the conditions were not intolerable. Then could a strike or the threat of a strike be justified by the probability of success? It had been said that all the cards were in the hands of the profession; he believed, on the contrary, that all the cards were in the hands of their opponents. It might be taken as an axiom that no strike had ever been successfully fought on a falling market. The case of the German doctors had been quoted, but they fought on a rising market. Here the market had been falling for the last two years. Under such circumstances even to threaten a strike was a technical and strategic error. He agreed with everything stated in M.I.; he did not think 9s. 6d. enough; the profession ought to have more, and at some future time it might get more, but he was sure that no more was obtainable at the present moment. Again, no strike had been successful in this country or anywhere else which had not a fairly good proportion of public opinion behind it. This, again, was axiomatic in industrial struggles. But he doubted whether public opinion would support the profession; the press was almost unanimously against it. (Cries of dissent.) In Parliament, while the profession would have the support of certain individuals in the Liberal and Labour parties, it would have no support from any effective section, and the Government supporters would be solidly behind the Minister. It had been stated that there were three factors concerned: the Ministry, the approved societies, and the profession; but there was a fourth, the Treasury, which was out to cut down expenses to the last. He differed from the view that unless they fought and won now they would be delivered over into the hands of the approved societies. What he did believe was that if they fought and were defeated they would be delivered over into those hands. The approved societies were spoiling for a fight on this issue. They wanted nothing better than a doctors' strike. Some of the leaders of approved societies had not repressed their exultation at the prospect. They anticipated that the Government in that event would hand over 7s. 3d. a head to them, and the club system would practically be reintroduced.

Dr. E. A. GREGG did not agree with Dr. Salter's forecast. There was no organized opinion in the party in power at the present time which was against the doctors. In many cases the member of Parliament held his seat owing to the activity of political bodies in his constituency of which a local doctor was the chairman or a prominent member. Again, the Ministry was not anxious to place into the hands of approved societies this great instrument for the uplifting of the public health. The Minister, in his reply, had mentioned the case of civil servants, but he omitted to state the many respects in which the civil servant servants differed from that of the doctor; the civil servant had sick pay, payment during the long annual vacation, and a pension on retirement, and he did not have any of the professional expenses to which the doctor was subject. The only point of validity in the Minister's reply was his comparison of insurance remuneration with the remuneration which doctors received from private and from other contract practice; he did not mention the fact that in many of these cases the charitable motive entered, a motive which should not be the basis of a State service. The speaker

reminded the audience that a very serious factor in the situation was that if the insurance capitation fee were reduced many other fees would fall with it. At the moment the profession stood at the cross roads. London was more or less suspect in the country, and he pleaded with those present that it must never be said afterwards that this fight was lost—in London.

Dr. BRACKENBURY, who was received with applause, said that he had come straight from addressing at Hatfield the largest meeting of medical practitioners ever held in Hertfordshire. There he had been asked, "What is London going to do?" He told them that he believed London was going to stand firm. (Applause.) Coming down to what he called the stark realities of the situation, he said that it was not a question of reopening negotiations now and sending in resignations as a last resort. The thing to be done was to secure a sufficient number of resignations, and upon that basis negotiations would be reopened and there would be a new opportunity of arriving at a decision which some would consider satisfactory and others doubtless still unsatisfactory. He denied that there was any such parallelism with an ordinary industrial dispute as Dr. Salter appeared to suppose. If practitioners resigned from the insurance service it did not mean that they ceased work. They were prepared to treat the insured persons on the lines of private practice at ordinary fees, which were customarily lowered in the case of the poor, and forgone altogether in the case of the absolutely necessitous. To say that resignation from the insurance panel corresponded to a strike in which the men engaged in some industry ceased to work was a perversion of the situation. All that was meant by the present attitude of the doctors was that they refused to accept certain conditions which were imposed upon them; they knew that they must suffer thereby and lose income, but they would rather face that than accept anything which they considered dishonouring to the profession. (Applause.) In the face of that question of professional honour, the economic question took a second place, and was one which he would not argue on that occasion. Whether they received sixpence more or less, whether they received it for three years or five, was a very important matter to them collectively, but it became relatively unimportant beside the question of self-respect and the maintenance of professional freedom. (Applause.) He differed entirely from Dr. Salter when the latter said that the self-respect of the profession was not in question in this struggle. Nobody could accept the conditions which they were now asked to accept without loss of self-respect and the damage of honourable traditions. If the profession submitted now, it was to the approved societies that it would submit. If it fought unsuccessfully, he agreed with Dr. Salter that it would be handed over to the societies. The only solution was a successful fight. (Applause.) They were in the hands of the approved societies now. The societies had actually said to the Minister that he had no right to give a penny of this money to the doctors or anybody else without their permission. Was Dr. Salter, as a true democrat, going to tolerate such usurpation by any section? It was a position intolerable, not merely to the profession, but to the general body of citizens. The societies had said, in effect, "We will permit the Minister to offer you eight shillings. You really ought not to have it; you ought to have only 7s. 3d., but by a majority of one on our Council we have decided that we will permit the Minister to offer you 8s. on this occasion. Only, remember, after that is given our grasp will be tightened, and if eventually you get 7s. 3d. you may consider yourselves lucky." He believed (again contrary to what Dr. Salter had said) that there was an increasing volume of both public and press opinion behind the case put forward by the profession. In this connexion he would refer Dr. Salter to an admirable article in the *Statesman* of October 13th. At the moment the societies were banking on the failure of the profession, and the Minister, who had been unduly impressed by the societies, was waiting to see. If these terms were accepted the position of those who spoke for the profession as a fighting force or negotiating power was gone. The grasp of these new masters would be tightened upon them, not only in the

honorary fellowship of the Edinburgh College  
gazetted K.C.I.E. on June 4th, 1921, and  
he left India on January 1st last. While  
he was also a member of the Council of  
a. He married twice—first, in 1896, the  
late W. H. Darley, of Deep Castle, Kings

ed in 1841, and secondly, in 1849, the widow ut-Captain Robert Bird, C.E., I.M.S. A ce was held at the Savoy Chapel on general Sir William Edwards had a trying

and would in any circumstances have  
d to follow. But Edwards had to face  
a kind Lukis never knew. Within a few  
appointments as director-general the famous  
in constitutional reforms by Mr. Montagu,  
General, was published. The object in view  
General, and Lord Chelmsford,

in large measure government and administrative hands of Indians, by establishing a Legislative Assembly for all India, and eventually signatures in all provinces, and eventually

resting complete popular control in local bodies. Among the subjects to be transferred at the earliest possible date

and the prospects of its officers would be very seriously affected. Elsewhere, of course, loyalty accepted the decision of the British and Indian Governments and devoted his best energies to making the transition work smoothly while safe-

Medical Service was able to state at the dinner of the Indian Medical Service officers of his own Service. He made a statement to the effect that the Secretary of State in Council had made regulations reserving for officers of the Indian Medical Service a total of 365 civil posts, thus providing employment for 338 I.M.S. officers, including leave and

These regulations, which are to be filled by the State and District health authorities, are to be approved by the State and District health authorities. These regulations, which are to be filled by the State and District health authorities, are to be approved by the State and District health authorities.

open to I.M.S. officers in the future, imply also that the Government intends to maintain the service, though with a smaller cadre. They are, however, provisional and are to be without prejudice to the final orders to be passed by the Secretary of State in Council when he has received and considered the report of the Royal Commission which is about to be published.

to go to India under the chairmanship of Lord Lee of Fareham, to inquire into the public services, including those of the Indian Medical Service in civil employment. Sir William Edwards protested at this dinner that the reorganizations did not go far enough in reserving appointments to professors, to alienists, as clinical

We imagine that Edwards was in certain other respects disappointed by the Secretary of State's decision, but he had not failed again to put up with it.

The following table shows the results of the regression analysis for the dependent variable "Attitude towards the environment" (scale 1-5). The independent variables are "Age", "Gender", "Education", and "Income". The table includes the coefficient estimates, standard errors, t-statistics, and p-values for each variable.

India, he had many friends and acquaintances in the country and had been spared abroad to serve that country as a representative of the Government of India on the Permanent Committee of the Government Bureau of Public Health.

The death is announced of Dr. Michael Thomas Sadler, who practised in Ramsey and its neighbourhood for forty-four years. He was born in 1834, and after receiving his preliminary education at Wesley College, Sheffield, became

also in the University of Edinburgh. He graduated B.A. Lond. in 1853, took the M.B. degree (with honours) in 1857, and the M.D. in 1861. He was consulting physician to the Beckett Hospital, Bursley, and medical officer of health for the borough and the surrounding

Dr. Sadler was a man of wide culture and public spirit; assiduous, within the limits of his leisure, in foreign travel; and a careful student of French and Italian literature. At one time he knew by heart *Paradise Lost*, the first part of *Ramus*, and Dante's *Inferno*, and used to repeat passages to himself during his country drives. After

His father, who bore the same name and was also a doctor in Barnsley, of the Charity Organization Society.

Sir Ralph Sadleir (1507-67) and another of his forebears, of Huguenot descent, Dr. Sadler traced his lineage from

## INSURANCE COMMITTEES AND MEDICAL BENEFIT.

SIR W. GLYN-JONES'S ADDRESS.

WE have been favoured with a summary of the presidential address to be delivered to-day (Friday, October 19th) by Sir William Glyn-Jones to the annual meeting of the National Association of Insurance Committees. The President's remarks have an important bearing upon the present fight by the medical profession for freedom from Friendly Society control.

Sir William Glyn-Jones will invite the delegates to consider how far after twelve years' working the promises of the Insurance Act have materialized, and particularly whether Insurance Committees are performing the functions allotted to them by Parliament and whether the duties at present performed by those committees justify their continuance. In so far as the Insurance Acts provide direct personal and individual benefits such as medical treatment, maternity benefit, and sick pay, he maintains that the contracts have been in the main fulfilled. Insured patients are better served and the doctors better paid than they were, and, though neither should be compared with the improvement in service and pay as compared with the situation prior to 1911 would in itself justify the Insurance Act whilst Insurance Committees have played a great part in the work accomplished, Sir William Glyn-Jones argues that they have not been given the responsibilities nor exercised the powers to them. The Act gave to Insurance Committees the nature of medical benefit and of all additional benefits as to the amount to be paid in respect of medical benefit. All these negotiations have, however, been conducted by the Ministry. Insurance Committees and Societies were told what the arrangements made were and had to abide by them. W. Glyn-Jones admits that collective national bargaining in cases was inevitable, but the fact remains that the powers Parliament entrusted to committees were not and never have been performed by them. They did useful work in connexion with sanatorium benefit whilst it lasted, but since May, 1921, the administration of this benefit had not been a duty of Insurance Committees. The scheme for the administration of the benefits for deposit contributors was a temporary one, to last until January, 1915, a date now extended to December, 1924. No one is satisfied with this part of the scheme. Whilst certain additional benefits of the nature of medical benefit have been provided for a portion of the insured persons, notwithstanding that the Act imposed the duty upon Insurance Committees. No additional benefits have been administered by Insurance Committees. The President next emphasizes the fact that the Government in promoting the National Insurance Bill of 1911 urged in favour not only its insurance features and the provisions in the bill for reducing sickness and disablement by removing their preventable causes. Great promises were held out of the improvement in the health of the community which would result if Parliament and the country accepted the bill. The executive of the Association of Insurance Committees has expressed the opinion that whatever might be said about the working of the scheme in the direction of insurance and treatment, the other promises have not been fulfilled. Sir W. Glyn-Jones supports his contention by extracts from the speeches in Parliament during the passage of the bill by Mr. Lloyd George and Lord Haldane. While imputing neither motive nor intention, he asserts that Insurance Committees could be in no worse position had it been the deliberate policy to blanket them, and by regulation to deprive them of all the power and responsibility given them by the statute, and to leave them with such a modicum of routine duties as to justify their being put to a peaceful and painless end. Making every allowance for the war and its aftermath, and the setback thus given to the work of Insurance Committees, he considers that it is reasonable, five years after the armistice, to ask the Government if and when Insurance Committees are to perform the duties for which they were created. The present position of Insurance Committees is, he holds, one in which they cannot with self-respect continue; and he asks in conclusion: "Does the Government think the work outlined for us should be abandoned or that we are not the bodies to perform it? In either case let us and the country know. We cannot with self-respect continue to be parties to a sham fight against the evils which we were enrolled with such a flourish of trumpets and beating of drum to combat." The outgoing Executive Committee directed attention to this aspect of the work of Insurance Committees, and the President asks the conference to give a mandate to the newly appointed executive to force the issue.

## RANGE OF SERVICE.

THE following communication, dated October 16th, 1923, has been received from the Ministry of Health:

A conference, presided over by Sir Arthur Robinson, the First Secretary to the Ministry of Health, accompanied by other officials of the Ministry, took place to-day (Tuesday) between representatives of the Consultative Councils of Approved Societies and representatives of the Insurance Acts Committee of the British Medical Association. The conference met to discuss certain outstanding questions relating to the scope and character of the service to be provided by insurance practitioners. The question of the remuneration of insurance practitioners was not discussed.

Sir Arthur Robinson reported to the conference that some misunderstanding existed in regard to a statement attributed to Dr. Brackenbury, the chairman of the Insurance Acts Committee, and said to have been made by him at a conference of Local Medical and Panel Committees, held on June 7th, to the effect that the Insurance Acts Committee could not agree to the claim that every practitioner should do for his insured private patients. In order to remove any misapprehensions in this matter, Sir Arthur Robinson quoted the exact words used by Dr. Brackenbury, which were as follows:

"Everything which was, properly speaking, of a general practitioner kind should be within the service, and everything which was properly of a specialist kind, whether performed by a man who did that thing only, or by a general practitioner who had made himself specially skilled in that thing, should be outside the service. This division had been attempted by the Insurance Acts Committee in the form of two schedules, one showing the services included in the contract, the other the services not included. What a general practitioner did as a specialist was outside. The claim that every practitioner should do for his insured patients all the things which he was accustomed to do for his private patients was not one to which they could agree for one moment. In so far as a general practitioner was in any degree a specialist, his specialist services were outside the contract, and he should have a right to charge for them."

## LONDON PANEL COMMITTEE. SPECIAL MEETING.

A SPECIAL meeting of the London Panel Committee was held on October 11th to consider a report of the Finance and General Purposes Subcommittee on matters relating to the Annual Conference of Local Medical and Panel Committees, which is being held as we go to press. Dr. H. J. CARDALE presided over a very large attendance.

It was agreed unanimously to instruct the representatives of the Committee at the Conference to move, as an instruction to the Insurance Acts Committee, that steps should be taken to ensure that no inequity as between practitioners should arise in the matter of payment during any quarter. On the question of the procedure of Medical Service Subcommittees, a former resolution of the Panel Committee was re-emphasized, expressing the view that provision should be made in the regulation whereby a term might be placed upon the period during which an Insurance Committee should notify persons complained against of the receipt of such complaints. Dr. BRACKENBURY said that this was one of the matters which was still at a loose end. In the present regulations there was a time limit of six weeks during which the insured person had to make this complaint; it had been pointed out to the Ministry that this was not quite the same thing as giving notice to the practitioner concerned that some complaint had been made against him. The Ministry's final words on this regulation had not yet been received.

It was also agreed unanimously to support the Insurance Acts Committee in its refusal to accept the obligation that a practitioner should stamp certificates with his name and address.

## The Capitation Fee.

The Subcommittee reported that in its view the Minister had not adequately answered the case presented to him by the Insurance Acts Committee; many relevant facts contained in the Committee's statement (M.1) had been ignored or evaded. The Subcommittee recommended:

That the offers of the Minister of Health of a capitation fee of 8s. for five years or 8s. 6d. for three years be definitely rejected.

This was immediately carried unanimously and with applause. The CHAIRMAN said that the rejection of these terms meant a fight, in which and the preparations for which a special responsibility would fall upon the London Panel Committee. He was convinced that if the London Panel Committee took

differences in some amino acid protein, such as arg, dog, horse  
 plantain, or some article of food. Systematic testing of skin  
 reactions would be the best way of determining the agent  
 responsible for the allergic reaction in this respect. Moreover  
 might be added to the list of allergens in the British  
 Association of Allergists, 1951, 1952. Such a list, compiled  
 recently of the various allergens and experimental evaluation of  
 possible cross-reacting articles of diet might be more helpful in  
 the diagnosis.

for the cardiac cripples from that city. Some of these are in special cardiac homes such as Dr. Miller advocates; others are in convalescent homes where special beds are reserved for cases recommended by the Heart Association. The need for such special heart homes would have to be placed before the charitable public, and to meet with satisfactory response it would need to be pressed with a weighty consensus of medical opinion. This would be one of the advantages of concerted action such as has been suggested.

Between the hospitals and the patients' homes there would always remain a gap, and this might be efficiently bridged by following up the children who leave hospital and who do not get institutional care by securing their attendance at special cardiac clinics, so that the earliest indications of relapse might be recognized and the lives of the patients guided along physiological channels. There has been sent to us by the Committee of Cardiac Clinics of the New York Association notes on its scheme of cardiac clinics, a synopsis of which we print in another column (p. 729). We do not suggest that it is necessary to follow the same lines, but the scheme is of interest as an indication of the thoroughness with which the matter is being taken up across the Atlantic.

It is not our province to prejudice the attitude that the Council of the Association will adopt to the request for the appointment of a special committee, but there can be no doubt about the importance of the issue. The figures supplied by the medical officers of the Board of Education are a sufficient indication of its magnitude. It would appear to be a case where united action is indicated. The Medical Research Council is already dealing with one aspect of the subject; school medical officers have to take cognizance of its presence, and in some instances have had to arrange for the education of affected children in other than ordinary schools; isolated attempts have been made in different parts of the country to provide institutional treatment of a special kind, but to an extent that only touches the fringe of the problem. How much has been done in the past to inculcate into the minds of the students of medicine the natural history of the disease in such a way as to open their eyes to the possibility of preventive measures it is difficult to say. Much more must be done in this direction if medical students are to enter the profession imbued with that appreciation of the significance of the preventive aspect of medicine which the General Medical Council desires. In many parts of the country the lay public are ignorant of the possibility of rheumatism as an affection of childhood or of its relation to heart disease. When one hears that in a school like Eton, to which we have already referred, about 1 per cent. of the boys give a history of rheumatism and that heart disease is rare, while in some schools under the education authority about 1 per cent. have rheumatic heart disease, the prevention of heart disease becomes a problem well worthy of attack by all the weapons at our disposal.

### THE HARVEIAN ORATION.

It has always been a tradition of Linacre's college to honour and cultivate classical learning, and in Professor Starling's audience on St. Luke's Day some must have recalled Tully's noble panegyric,\* and in

recalling the great Roman's words must have applied them not to the *doctrina* Tully had in mind, but to the wider *doctrina* of which Professor Starling's discourse was the fruit; the *doctrina*—we had almost written the gospel—which inspired him to say, "I feel that I have had the good fortune to see the sun rise on a darkened world, and that the life of my contemporaries has coincided not with a renaissance but with a new birth of man's powers over his environment and his destinies unparalleled in the whole history of mankind."

This *doctrina* can only be possessed by one to whom Harvey's injunction to "search out the secrets of Nature by way of experiment" is an absolute rule of life, not merely a stimulant of rhetoric.

Many do lip service to the cause of "research" whose lives and actions are far more hostile to the real searching out of Nature's secrets than any of the traditionalists who fought against Harvey, for many of these did have a passion for truth, and erred from deficient plasticity of intelligence rather than from a false or base choice of object. Those who now clamour for the direction of research to "practical" objects have none of the excuses to be urged in behalf of the anticirculationists, not even that of loyalty to the teaching of a great master. "For the full and untrammelled exploitation of the advantages of the experimental method it is essential that mere material advance shall not be the target of our ambition." These are Professor Starling's words. The story of progressive comprehension of the manner of functioning of the heart in health and disease, the account of the correlation between all organic systems and of its material basis, two chapters of the book of life many pages of which have been inscribed by Professor Starling himself, are worthy comments upon the text.

The sermon is on an old text; it has been preached by the words or exemplified in the lives of all the men the Orator named—Boyle, Mayow, Hales, Cavendish, Lavoisier, Bernard, Pasteur. All studied out the secrets of Nature, not over-curiously considering whether the precise secrets which fascinated them held or did not hold the clue of some practically important mystery. In these days, when great wealth and power are often in the hands of well intentioned but ignorant men, the scientific worker is subjected to a temptation not so severe as confronted his spiritual ancestors in the Middle Ages, but severe enough. No student of Nature's secrets now runs the risk of being burnt alive. But he must often choose between hopeless poverty and obscurity on the one hand and spiritual slavery on the other. It may often be quite good business to sell one's soul; it is obviously better to sell it than to lose it like Peter the Politician in Mr. Belloc's story. The statistical probability that the most disinterested student of Nature will become a Lavoisier or a Pasteur is extremely small, and the chance that his wife and family will enjoy as many of the material advantages of life as the dependants of a fairly prosperous grocer is not much larger. The director of the X.Y.Z. Institute for Research into Diseases of the Great Omentum may be a prosperous and happy member of society. He has lost nothing but a very small chance of becoming one of the *servi servorum* commemorated in a Harveian Oration.

Simony is, after all, not purely an ecclesiastical offence. Simon Magus, when he saw "that through laying on of the Apostles' hands the Holy Ghost was given," offered them money, saying, "Give me also this power." Peter rebuked him, saying, "Thou hast neither part nor lot in this matter." It is

\* Nam ceterae neque temporum sunt neque aetatum omnium neque locorum; at haec studia adulescentiam acunt, senectutem oblectant, secundas res ornant, adversis perfugium ac solacium praebent, delectant domi, non impediunt foris, pernoctant nobiscum.

Victor Horsley Memorial Lecture  
TO  
THE RELATIONS OF SURGERY AND

အကျဉ်းချုပ် ဖော်ပြချက်

Sir EDWARD SHARPEY SCHAFER, F.R.S.,  
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF EDINBURGH.

PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF EDINBURGH.

DELIVERED ON OCTOBER 25TH, 1923,

It kept it a peculiar honor to have been asked to give the first Victor Horsley Memorial Lecture. I had the less hesitation in according to the request that I should do so because I am not only his oldest surviving scientific friend, but also his first fellow worker. It is nearly half a century ago that he made his appearance as an eager, intelligent student in the old Physiological Laboratory at University College. Sharpey had but recently retired from the teaching of physiology, although his personal influence was still felt. His place had been taken by Burdon-Sanderson, whose dominant idea was to make the study of the subject

work of the famous experimental psychologist, and many of us who know Victor Horsley will readily understand with what keen interest this idea would inspire him. There can indeed be no doubt it was this training in experimental physiology which determined Horsley's future as a physiologist and as a scientific surgeon. And yet it is this double career which may be regarded as the example of the mutually beneficial influence of surgery and physiology. I have almost been tempted by one long and intimate

friendship, which began so unapologetically at University College in 1875 and lasted until the day of his death in 1910, to dwell, on this the last opportunity of commemorating his career, his mode of personality which was so striking a feature of his character—his enthusiasm, his love of truth and honesty of purpose, his energetic striving for everything he judged to be right.

to be right and therefore wrong. But has not all that been done far better than I or anyone else could hope to do it, in the history which Mr. Stephen Fager has set forth in that admirable style which characterizes all his writings? It is fortunate that the life of Victor Horyay was such a biography; nor was the biography less fortunate in having such a subject? How splendidly has taken

"I have chosen 'The Relations of Surgery and Physiology' as my opportunity we all of us know. I make the text upon which to base the remarks I have to make to-day. It is my object to show that these subjects are mutually dependent; that Physiology must call in the aid of Surgery to solve many of its most intricate problems, and that Surgery cannot make any real advance unless it proceeds hand in hand with Physiology."

It was not Horsley himself who established this principle, but he happened upon the time when it was beginning to be evident. Only a few years before, it might have been admitted that there was a certain amount of interdependence between Medicine and Physiology, but no one would have thought of connecting Surgery with anything about anatomy. That experiments on animals were necessary in order to elucidate the functions of the body was a maxim in order to elucidate the functions of the body.

[illegible]

information which would be useful to them in the performance of similar operations in man, nor should I be surprised to hear that there are some who still hold this view. It is fortunate for the world that Victor H. was not one of these.

As I have remarked, he happened upon a time when the importance of animal experimentation was beginning to be recognized. There were two directions in which this tendency was particularly apparent. One of these involved the investigation of the functions of the brain; the other those of what we now term end-organs—those of which more than for the most part, completely obscure. And it was just these two subjects that attracted the attention of the physiologically trained, hitherto unknown young surgeons whose work was to bring so much light upon these dark places of the brain. It is on this account that I propose to deal with these particular aspects of the question of the relationship of Surgery and Physiology. I will begin with the relationship of the functions of the brain and its related subject, craniotomy.

THE FUNCTIONS OF THE BRAIN AND CEREBRAL STRUCTURES

Not very long before the entry of Victor Horsley into the University College as a medical student, a young Swiss physician named David Ferrier published an elaborate series of researches on the results of electric stimulation of the cerebral cortex in animals. Some of these were of a kind which have been since performed on the dog and cat. Ferrier and Hitzig, although the method of stimulation employed by Ferrier was a vast improvement on that used by the German observers. But what rendered Ferrier's researches really important was the fact that he extended his researches to the brains of monkeys, which are entirely different in the conformation of the cerebral cortex to the brains of the dog and cat, but present a remarkable resemblance to the brain of the highest member of the order Primates, man. It is scarcely necessary to say that the brilliant experiments of Ferrier aroused much interest. I shall myself never forget the impression upon me by one such experiment which Ferrier showed Burdon-Sanderson and the rest of us who were working in his laboratory. The convenient way in which he could direct what would be the movement resulting from touch of that portion of the cortex with the electrodes demonstrated always provokes the same feelings in the animal to arouse one wonder and admiration; and to remove the tumour or to deal with the source of injury with advantage to the patient.

In all researches in experimental physiology, there is much with advantage to the patient.

and to remove the tumour or to deal with the source of injury with advantage to the patient.

located the seat of an injury and tumour in the human brain. The chimpanzee and gorilla—which have enabled the surgeons to remove the tumour or to deal with the source of injury with advantage to the patient.

results obtained by Sherrington and Grünbaum upon the orang, and by the yet more recent and accurate observations of Horsley and Bevan on the human brain. It was these experiments—supplemented as they were by those of Horsley and Bevan on the human brain. It was these experiments—supplemented as they were by those of Horsley and Bevan on the human brain.

[illegible]

this opportunity of making its freedom sure. If this is ever to be done it must be done now. There should be no doubt about the decision, and it must be shown by immediate action. The only course now open is for the profession to show that no service can be secured under the Acts, whatever the exact terms, until the professional position has been re-established. This means that every insurance practitioner should at once send to the secretary of his Panel Committee his resignation from the service, to take effect on January 1st next. If the resignations are so secured by October 30th it will be possible for the Insurance Acts Committee to resume negotiations with confidence, and it may be taken as certain that, the freedom and honour of the profession once secured, there is not likely to be serious difficulty in reconciling the interests of the profession with those of the insured population and of the whole community, which must, of course, be paramount.

The public may be assured—and we believe it is fully assured—that whatever the course of the conflict precipitated by the Ministry of Health may be, members of the medical profession in their individual capacity will not cease to render service to individual patients, whether insured persons or otherwise.

#### THE WESTMINSTER HOSPITAL.

THE Westminster Hospital, which is one of the landmarks of London, is about to be rejuvenated. The hospital grew out of a small infirmary established in 1719. The present site was acquired from the Treasury in 1830, and the building erected upon it by voluntary subscriptions was opened in 1834. The cost of the work now in progress is estimated to be £70,000, of which amount £20,000 has been promised; an appeal is being launched this week for the remaining £50,000. The object is to reorganize the wards, supply modern accessories, provide a home for the nurses, and generally to bring the services up to date. No appeal for such purposes has been made by this hospital within the last fifty years. Before the war a proposal was made to remove the hospital to Clapham; apart, however, from the objection of breaking old associations the comparative cost proved to be the decisive factor. It was found that to construct a new hospital would mean a vastly larger expenditure of money under present conditions than could be obtained by the sale of the site at Westminster. Consequently a few months ago it was decided to carry out the alterations indicated and the hospital was closed last July. It is hoped, however, that it may be reopened in March. Meanwhile out-patients are being treated in Caxton Street, where the medical school of the hospital is situated. Mr. W. G. Spencer, senior surgeon to the hospital, has written for the hospital magazine a history of the hospital and its medical school. Reference to the medical school in the minutes of two centuries does not actually occur until 1834, when allusion is made to a private purchase of a site in Dean Street (now Great Smith Street) at a cost of between £2,000 and £3,000. This school was maintained for a period without formal recognition by the governors. There are accounts later on of undertakings more or less officially backed, but not until 1885, when the existing premises in Caxton Street were opened, does the operation of the school play a prominent part in the life of the hospital. The records of successive members of the medical staff include the names of five who in turn held the position of President of the College of Surgeons. Amongst the early physicians were Benjamin Hoadley, who gave the Goulstonian lectures in 1737, was Harveian Orator in 1742, and was physician to the King's household and to the Prince of Wales; Sir

Richard Jebb, physician from 1751 to 1762, who was Harveian Orator in 1774, attended George III, and left behind him many stories of his eccentricities; and Hamilton Roe, another Harveian Orator, who had much to do with the founding of the medical school. The beginnings of the nursing staff were humble. Mrs. Jane Allen, the first matron appointed, at Christmas in 1719, to take charge of the small house in Petty France in which the first infirmary was conducted, was paid £6 per annum, and had the assistance of one nurse at £5 14s. and a maidservant at £4. In addition an old woman visited out-patients, and there was an indoor messenger youth. The number of in-patients varied from eight to twelve, and there were about as many out-patients. The first mention of the employment of a night nurse occurs in 1733. The hospital is now one of the institutions of London, drawing many patients from the poor district between the Abbey and Vauxhall Bridge, and from a still wider field. Its medical school has educated many men who are now practising in all parts of the British Empire. During last year the number of in-patients was, in round numbers, 2,500.

#### THE AIR AMBULANCE IN WAR.

IN his presidential address to the War Section of the Royal Society of Medicine on October 8th, Air Commodore D. Munro discussed the possible uses of the aeroplane in the medical services in future warfare. The history of the air ambulance, he said, began necessarily with improvisations, by which he meant the temporary use of an ordinary service aeroplane to carry sick and wounded, either with no special arrangements at all or only primitive ones, or with a special kind of stretcher adapted to the machine, or a special adaptation of the machine to take the ordinary stretcher. During the retreat of the Serbian Army in 1915 the French made some arrangements for air convoy of wounded. At the end of 1920 the French in the Levant organized an air ambulance in which eighty cases were carried to hospital during a period of four months. For this purpose the machine guns were removed from aeroplanes and the patients strapped in their place. In May, 1923, during an epidemic of dysentery among the British forces in Kurdistan, 198 cases were conveyed by air to Baghdad. The distance was 100 miles as the machine flies, and was much longer by mountain track, which would have had to be taken had the aeroplanes not been available. The operation was difficult owing to bad weather and the lack of suitable landing places, but it was carried out quite successfully in 98 flights; the time occupied in the evacuation was 128 hours 45 minutes. Unfortunately the only aeroplane specially designed for this work had to make a forced landing and was put out of action, so that the task was completed by improvised machines. The special kind of stretcher used with the service aeroplane was of a naval pattern, adapted to aeroplane purposes by the use of an extra lining. It consisted of bamboo sticks in canvas, with a head cushion, a blanket cloak, and a head and face mask. The squadrons in Egypt and Iraq were now supplied with these stretchers for use in emergencies. They were strapped on to the fuselage, and the machine-gun fitting was used for fixing in position. If necessary two patients could be carried in the one machine. The adaptation of the aeroplane itself to accommodate the ordinary stretcher was carried out during the Somaliland expedition of 1919-20, when a machine, known among the troops as the "blood-wagon," was altered so as to take one stretcher and an attendant. The French in Syria and in Morocco had a regular service of such adapted machines, and it was reported to the French Colonial Congress of Public Health in 1922 that in the former country 105 casualties and in the latter country 168 had up to then been conveyed in this manner without mishap. In 1921 the

The facility with which he used either hand contributed not a little to the dexterity of his operations, and he never, in any circumstances, lost the sang-froid which is essential to the surgeon.

#### THE RECTIONS OF THE THYROID GLAND.

Although by the work which Horsley had done upon the brains of monkeys and apes he had become one of the most skillful and scientific operators upon that part of human anatomy, he was much too all-round a man to confine himself to a single object, and we must next follow his career in another subject—that, namely, dealing with the functions of the thyroid gland, to which he brought equally keen enthusiasm for physiological investigation and skill in surgical procedure. Like that upon the functions of the brain, this also has an interesting preliminary history.

The year before Victor Horsley was born, Moritz Schiff of Geneva, one of the most active physiologists of the middle of the last century, had published the results of observations he had made upon animals, the thyroids of which he had extirpated. But at that time neither physiologists nor medical men were prepared to take much interest in the thyroid, not indeed in any of the so-called ductless glands, which now under another name occupy so prominent position both in physiology and in clinical medicine. Schiff's work, therefore, which was not without interest and importance, passed unnoticed, and the matter was allowed to rest for many years. But just about the time that Horsley was starting his surgical career, the subject of the thyroid and its functions had come into prominence on account of the fact that it was becoming the practice amongst surgeons in Switzerland—in which country the tumours of the thyroid are common—to remove such tumours entirely when they were inconveniently large. In such cases of complete removal very serious symptoms resulted—symptoms which closely resembled those which had been described some ten years previously by Sir William Gull as a cretinoid condition of adult life, and were later shown by Orlé to be associated with absence or atrophy of the thyroid. Orlé applied the term "myxoedema" to the syndrome. The symptoms resulting from thyroid removal were recognized by the Swiss surgeons J. and A. Reverdin as resembling those of myxoedema, and they gave to them the name *operative myxoedema*. Th. Kocher, who described them at about the same time, spoke of the syndrome as *cachexia strumipriva* or *thyropriva*, the name by which it is now generally known, although the term "operative myxoedema" best describes its cause and symptoms. These observations of the Swiss surgeons were published in 1883, and led immediately to a great revival of interest in the thyroid both amongst physicians and clinicians. Schiff himself repeated and extended his old experiments, and many other physiologists took up the subject, interest in which is indeed by no means exhausted even at the present day.

How Victor Horsley came to start experiments upon the thyroid is narrated by Paget:

"On November 25th, 1883, at a meeting of the Clinical Society of London, there was a discussion over a case of myxoedema shown by Dr. Dewitt, and Felix Semon called attention to Kocher's observations and said positively that cretinism, myxoedema, and cachexia strumipriva were closely allied conditions, having in common either absence or more probably complete degeneration of the thyroid gland; and that they could hardly be attributed to any other cause. On December 14th the Clinical Society appointed a Committee to investigate the whole subject. Orlé was Chairman. Hadden was Honorary Secretary, and Horsley was a member of the Committee.

"It was of necessity that the investigation should include an experimental study of the healthy gland in healthy animals, and recognizing the inherent undream of importance of the thyroid gland," they asked Horsley to study it by the experimental method. They needed a physiologist and a surgeon, and they had them in him."

Horsley started this investigation in my laboratory at University College, working at first with William Godlee, who was also a member of the Committee. They made several experiments together upon monkeys: we had a number of animals specially prepared and warmed for keeping those animals. But very soon the work was transferred to the Wandsworth Road, Horsley being now professor super-

inconvenient to carry on work in both places. So he continued the investigation alone, and dealt with the results in the lectures which he was expected to give annually at the University of London, the first of these being published in the *British Medical Journal* in January, 1885, and the next in the *Lancet* in 1886. It is somewhat singular that, with the exception of two short notes communicated to the Royal Society, he never took the trouble to send the results of these experiments upon the thyroid to any scientific periodical, although they were mentioned in his annual reports to the Committee of the Brown Institution, and ultimately appeared in the report of the Committee on Myxoedema, published in 1888.

The reason for this silence on the part of an investigator like Horsley, who never in any other subject had the least hesitation in giving his results to the world, whenever they were sufficiently definite, was, I imagine, a certain indefiniteness and variability in the effects obtained from the removal of the gland. For some animals were simply rendered apathetic, with slow movements, a low body temperature, and a general debility in vitality; others showed acute nervous symptoms, with muscular tremors, which might pass into fits of greater or less violence, and terminate in death. Horsley himself seems to have thought that these were stages of the same condition. But we now know that the two kinds of symptoms were due to entirely different causes, as in the one case the thyroid alone had been removed, and in the other the removal had included the parathyroids. Unfortunately, at the date of these experiments, the parathyroids, although they had been described and named some years earlier, had not been recognized as organs having an entirely different function from the thyroid. It was only some years later (1891) that Ernest Gray, the eminent professor of physiology in the College de France, discovered this function, and showed that the symptoms of nerve excitation are entirely due to the removal of the parathyroids, and are not seen when these, or some of them, are left intact in removing the thyroid. On the other hand, removal of the thyroid alone without the parathyroids produces all the symptoms of cretinism and cachexia strumipriva.

The fact that when dealing with young animals the parathyroids (unless looked for, and they were at that time unknown) are more likely to be removed along with the thyroid (as age advances, some of them move further away from the thyroid) accounts for the circumstances that Horsley found most of his young animals died in a few days with violent nervous symptoms. In consequence of this he missed the very important point that the thyroid exerts a remarkable influence on growth and nutrition, including the nutrition of nerve cells; which is indeed now established as one of its principal functions. But we cannot blame him for missing this point, since our knowledge of the thyroid-parathyroid apparatus was not sufficiently advanced at the time.

#### THE PITUITARY BODY.

There is another important endocrine organ to which Horsley devoted a good deal of attention—namely, the pituitary body. He was, I believe, the first to endeavour to determine the effect of removal of this organ, for about 1886 he made one or two attempts to reach and destroy it through the pharynx and base of the skull. The conclusion he arrived at was that it is an organ which is not essential to life. Many years later he repeated these experiments and apparently saw no reason to alter his opinion, although in the meantime a number of other investigators who adopted other means of reaching the gland had come to an opposite conclusion. There is now no doubt that in most adult animals at least the loss of the pituitary body or even of its anterior lobe alone is incompatible with life, and had Horsley proceeded to attack the gland by the same (harsh) route as has been employed by most other investigators, a perfect asepsis can be ensured, he would, I am sure, have obtained the same results. His original method offers many difficulties from the inability to asepsize and sepsis, and from the impossibility of seeing what one is removing when working at the bottom of a deep and narrow hole.

Horsley was inclined to regard the results obtained by

screens or experimenting with incubators and agglutination baths, and afterwards reading modest papers before scientific societies, belong to the same breed as those in all generations who have subdued kingdoms, and wrought righteousness, and obtained promises, and stopped the mouths of lions, and quenched the violence of fire. They, too, have been content to die, many of them, not having received the promises, but having seen them afar off." A magazine article written in this sympathetic tone may act as a valuable corrective to the misunderstandings that arise from the somewhat hysterical accounts of medical researches that are published from time to time in other lay journals.

#### TENDENCIES OF PHYSIOLOGICAL SCIENCE.

PROFESSOR A. V. HILL, F.R.S., the newly appointed Jodrell professor of physiology at University College, London, delivered a lecture on October 16th on the present tendencies and future compass of physiological science. He said that physiology in Great Britain, though not in some other countries, was in the faculty of science as well as in the faculty of medicine, and to this he attributed much of its present high standing. It was not true that physiology was the handmaid of medicine any more than that physics was the handmaid of chemistry. Physiology, fundamentally the study of how the living creature worked, had its own needs and problems and methods; at the same time it was true that the utility of its results was largely in the field of medicine, to the needs of which no physiologist could be indifferent. The present tendencies of physiology were in some directions obvious. The unparalleled advances of biochemistry in recent years left no doubt as to one such tendency. Biochemistry was now passing beyond the study of the structure of matter that had been alive to the study of occurrences in the living cell. It would play a great part in the solution of such problems as the chemical nature of insulin, and perhaps its synthesis, the mechanism of immunity, and the elucidation of the accessory food factors. Differing from biochemistry only in technique and not in purpose as the development and adaptation of purely physical methods, including the design of instruments, of which he instanced the latest form of Einthoven galvanometer as representing the highest effort of the creative imagination. Along this road the effect of  $\alpha$  rays on living cells, the mechanism by which work was produced by the expenditure of chemical energy in the muscle, and the further study of the action of physical factors such as light, heat, and touch on the sense organs, awaited the investigator. The cautious application of the experimental method must continue to make for progress. The analysis of the living nervous system, the pancreatic, endocrine, cardiac, and other functions, all required experiments on animals. Now that the discovery of insulin had appeared as the result of animal experiment it seemed unlikely that there would be any immediate interference with experimental freedom, but in a few years' time, when insulin had become accepted as part of the medical armoury, the public might not remember the means by which it was elicited, and some apparently innocent legislation might be hurried through which would make further advance impossible. But it was strange how often a physiological truth, discovered in an animal, needed to be amplified by working it out on man. Man had proved to be the best subject in studying, for example, respiration and the carriage of gases by the blood. Moreover, experiment on man had the advantage that it led directly to what was required in medicine. Until the truth discovered in animals had been applied to man it had not, so to speak, attained its majority. It was necessary to build up a sound body of trained opinion versed in study

on man, which would prove of great service, not only in medicine, but in many directions in social and industrial life. The physiology of the future would take more advantage of zoology. This might not enter into the sphere of medical science, but it was physiology none the less. Zoology, of which physiologists had often been ignorant, had to offer in its greater elasticity of technique a new armoury of weapons, and perhaps its study might help to correct the tendency of some physiologists to forget the existence of the animal as a single organized whole. Histology, hitherto associated with physiology, might with advantage be surrendered to anatomy, to which it logically and properly belonged. The new physiologist was apt to be too busy with other things to bestow sufficient care upon histology, while the new anatomist, unlike his forerunner, had more interest in the investigation of the living body than in the dissection of the dead, and one of his natural methods of attack would be the microscopical study of the web structure of living tissue. Physiology was nothing less than the study of the mechanism of life in any form and by every means which science or the arts had to offer. Team work would have to be undertaken and organized investigations planned, but the opportunity must remain for that free and unfettered originality which the older and less businesslike methods so richly evoked. More than ever freedom would be needed, the liberty to investigate things because they were interesting, because inquiry into them was an adventure of the human spirit, because they seemed to lead to a solution of those fundamental problems which man in his intellectual impudence believed to be soluble. Professor E. H. Starling, who presided at the lecture, referred to his successor in the Jodrell professorship as the most distinguished physiologist of the new generation in this country. When he himself was considering whether he should apply for the Foulerton professorship of the Royal Society and resign his post at the mother school of English physiology, he felt much inclined to give up the direction of the institute, and then he remembered that if he did they could get Hill! For many years physiology did not represent a separate discipline at all; only comparatively recently had it been separated from anatomy. It had derived great illumination from the labours of chemists and physicists, and chemists themselves had come into its fold, but the special feature of the present occasion was that physiology could welcome as its "convert" a man who began as mathematician and physicist.

#### SMALL-POX AND VACCINATION.

THE publication by the Research Defence Society in the October number of its journal, *The Fight against Disease*, of an address given by Dr. John C. McVail to members of Parliament last July on small-pox and vaccination, provides an interesting statement which will be very helpful to any who are concerned with the education of the general public in this important matter. The value of the prevention of small-pox is illustrated particularly by the register of Kilmarnock in Ayrshire, which includes the causes of all deaths there between the years 1723 and 1764, during which period there occurred nine epidemics of small-pox; the inevitability of infection and the high death rate before the age of Jenner are apparent. The prevention of the disease by vaccination is set out and supported by evidence drawn from the conditions in Germany before and during the last war; furthermore, the importance of revaccination is clearly indicated in a table of incidence rates in four cities which are well known as centres of antivaccination activities, and also in another table of incidence of the disease in Glasgow during the epidemic of 1900-1. The impossibility of prevention without vaccination is succinctly demonstrated, and, although

its (1) etiology (nine titles given); (2) structure (twenty-nine titles given); (3) pathological physiology (twelve titles given); (4) functional capacity (four titles given). Thus a diagnosis might read: (1) rheumatic inactive; (2) mitral stenosis; (3) auricular fibrillation; (4) Class 3, much impaired activity; or (1) syphilitic, active; (2) aneurysm of aorta; (3) normal sinus rhythm; (4) Class 4, confined to bed.

The address of the Association for the Prevention and Relief of Heart Disease is 370, 7th Avenue, New York. The chairman of the Committee on Cardiac Clinics is Dr. William St. Lawrence.

## PUBLIC HEALTH IN SOVIET RUSSIA.

BY

L. HADEN GUEST, M.C., M.R.C.S.

(Continued from p. 679.)

### II.—THE CONDITIONS OF CHILD LIFE.

THE original intention of the Communist party in Russia was to apply a full programme of Communism in all departments of life. This, of course, included the children, about whom the Communists agree with Plato that they are the business of the State and not of the individual. Translated into action this meant the setting up of a large number of "children's homes" all over Russia, where the children were to live a communal life and be provided by the State with all the requirements of life. In practice the plan has not worked out so well as intended—the cumbrous organism of Russian bureaucracy could not adapt itself to new conditions—and the children in 1920, 1921, and 1922 lacked not only clothing and materials necessary for education, such as books, pencils, and paper, but, most important of all, they lacked food. In September, 1922, there were not less than 300,000 children on the verge of death from starvation. Foreign relief, Government activity, and the revival of free trade inside the country averted the worst of the evil, but the suffering of many children, in and out of the children's homes, was excessive. Many died, and a very large number were permanently injured. A good authority informed me that "all the children of the revolution"—that is, all children who were either very young in 1917 or have been born since that date—"are neurasthenic—interesting, but neurasthenic." But apart from this neurasthenia the effects of deficient feeding, of rickets, and of intestinal disorders caused by bad food, have left the mark of permanent injury on a great number of children. This injury may be compensated for by later developments, but it cannot be entirely obliterated.

Among the effects of this lower standard of life in 1922 must be counted the almost universal occurrence of scabies, *tinea tonsurans*, and *eczema*. There are also a very large number of cases of favus, and eye diseases are widely spread. Pediculosis is not to be mentioned, because it was practically universal in child and adult, as the typhus statistics showed.

The situation has had to be met by applying medical knowledge in a State-directed campaign which is already producing marked results. To begin with, certain difficulties and certain practical impossibilities have had to be recognized. In the first place, while I was not explicitly so informed, the principle of the communal children's home has apparently been abandoned, for it is stated that the number of children in such homes is now only 120,000, or less than half the child population of Moscow, and these children are spread all over Russia.

It was the original intention of the Government that all children attending schools, whether in a children's home or living with their parents, should be provided with clothing and food at the expense of the State. This plan has had to be given up, and neither clothing nor food is ordinarily so supplied.

There is the further difficulty of staffing a sufficient number of schools with teachers. Russia was extremely deficient in all trained personnel before the war—the Czarist Government being quite definitely opposed to the education of the masses—and the events of the revolution and civil war since then have made systematic training

very difficult. The difficulty is complicated by the Government's policy of secular education, as a number of teachers refuse to teach unless they are allowed to give religious instruction, and in the villages the peasants, who are very superstitious, refuse to pay for education unless they are allowed to have a priest to teach their children. This conflict is not settled or likely to be settled for some time, and it will certainly have injurious effects upon education.

The actual lack of personnel and the further lack of institutions make it impossible for the Government at present to deal with the many abandoned children, orphans and others, who have collected around all the large towns in Russia during the period of war, civil war, revolution, and famine. The very large mass movements of population which have occurred have inevitably led to the formation of this strange and sinister class of wild human beings. It is estimated that there are four or five thousand of these children in Moscow itself. They live in the woods around the town, and employ themselves in selling, in begging, and in sheer vagrancy. At night they flock into the large railway stations to sleep. Numbers of quite young girls are to be seen in the streets, selling scent and other trifles, and they stay there very late at night. Some of them are becoming prostitutes at a very early age. All of these abandoned children are growing up without control and without schooling, and they will be a very serious problem indeed in the future.

The number of tuberculous and syphilitic children in Russia is unfortunately very considerable, but these are now being separated from normal children and dealt with in special institutions. Leprosy is also common in Russia, and children affected with leprosy or the children of lepers are now separated from the others. A mere enumeration of these problems shows the tremendous problems Russia has to tackle, but, although her technical equipment of personnel and of institutions is less than normal, a great measure of success is being attained. The Russian medical service is, of course, a very good one, and it has worked extraordinarily well, but it is certainly to be hoped that it will now get assistance from other countries in work which, after all, affects other countries materially, especially those which come directly into contact with the Russian frontiers.

The measures mentioned up to the present are mainly negative in character, but it required great courage to take negative measures in a country so enthusiastic for its own Marxist ideology. But practical constructive steps have been taken as well. At present a considerable number of children are receiving food from relief agencies of one kind and another. Meals paid for by money which comes from the Pope are at present nourishing 6,000; it is not a very large meal, but one containing sugar, milk, and fat, and a very large number of all town children are provided for in summer in the country by a State-organized system of camps or colonies. The children live in the sunny climate almost completely exposed to the air, the clothing of both boys and girls being usually only a small pair of drawers. In the climate of Russia this is sufficient clothing in summer.

For the treatment of skin diseases the Commissariat of Health is now proposing to set up x-ray installations in the Crimea, at Moscow, and at Kharkov for the Ukraine.

It is quite obvious under the conditions just indicated that school medical inspections such as are carried out in Great Britain are, if not impossible, at least very difficult. But there is a medical service engaged in the work. There are about forty school doctors in Moscow, of which the school population is about 300,000, and there are special school doctors in other large towns. In the villages the doctors responsible for the medical care of the district have been instructed also to inspect the children in the schools. Gradually, therefore, as the preliminary classification and segregation of well and diseased children is carried out, it will be possible to proceed to the treatment and care of the ordinary ailments of school life, such as are dealt with in England and Germany. Under existing conditions, however, it is not practicable for the methods used in England and Germany to be carried out in Russia for a considerable number of years to come. For one thing, a large increase in the number of doctors will be required, and as the

CHRONIC INTESTINAL STASIS AND CANCER.  
An Address  
by  
SM W. ARBUTHNOT LANE, Bt., M.S., F.R.C.S.,  
CONSULTING SURGEON TO GUY'S HOSPITAL.

At present surgery and medicine appear to be one horrible mælie of attempts to understand and treat end-results, little or no endeavour being made to obviate the development of these conditions. In surgery operations increasing in severity replace less extensive procedures; whereas in such a condition as ulcer of the stomach, while no attempt is made to remove the factors which produce it together with many necessarily associated results, the possibility of the recurrence of the ulcer is only eliminated by the removal of the entire organ. The safety with which such operations can be performed, and the ease with which a surgeon can acquire sufficient skill to effect them at comparatively little risk, tend to increase the number and severity of these operations. Everyone worships the god "technique," to the complete elimination of the importance of dealing with the causation, and therefore the prevention, of disease which should be our real object in life.

The profession is only just beginning to realize the enormous part played by the defective functioning of the gastro-intestinal tract, the consequent fouling of the food supply, and the poisoning and deterioration of the tissues by septic material absorbed from the intestine.

That we pay dearly for the luxury we enjoy in our food and habits of life is shown clearly by the fact that civilization brings in its train a very large number of conditions which do not exist in those leading the simple life of the native. That these conditions are all due to acquired defects in the functioning of the gastro-intestinal tract is, in my opinion, undoubted, since they occur at once in the native when he is placed in a civilized community; and it can be shown that these diseases bear a direct proportion to the degree of civilization enjoyed.

Roughly the difference between the civilized and the uncivilized is a matter of diet. While the latter eat much food that is uncooked or only imperfectly cooked and which contains a large proportion of indigestible matter, the former eliminate from their meals all but the digestible. By this means the bulk of the food and its stimulating action on the intestinal wall are diminished as much as possible and the material stagnates and becomes poisonous. As evidence of these statements I will quote an extract from a lecture by a great observer, Colonel McCarrison. He spent nine years in the Himalayas, during which time he had a large practice, performing more than 400 capital operations each year. During that time he never saw one case of asthenic dyspepsia, of gastric or duodenal ulcer, or of cancer. He called your attention to this sequence, all evidence of chronic intestinal stasis, since I am certain that cancer is the last stage in the sequence, and that it never attacks a healthy organ. The diet of these people is very simple. They live chiefly on corn ground between stones. This is made into a cake which is imperfectly roasted over a charcoal fire. They very rarely eat meat. Mr. F. L. Hoffman the eminent American statistician writes to me as follows: "Your views regarding dietary or nutritional causation (of cancer) coincide with my own based upon extensive research among native races. I recently returned from a trip to South America, where I lived for seven months before the Guy's Hospital Physical Society, October 1913."

LISTERIAN METHODS IN SURGERY.  
I have often wondered what difference it would have made to my own life if Joseph Lister had been elected a member of the College even made. The echo of the name of Lister in my mind would have been a great deal more than one edition. Lister's physiology, although he published a textbook of physiology, I do not think it went through more than one edition. Lister's "technique" speaks of Marshall as scientific and a good teacher, but these are terms which I cannot endorse. I had a charming personality, and as he was already a member of the staff of the hospital he obtained the chair in reference to Lister, who had been many years away from the institution and was unknown both personally and through his work to most of the staff. John Marshall became a Fellow of the Royal Society and President of the Royal College of Surgeons. There is an admirable bust of him at Lincoln's Inn Fields. But Lister's name will be famous when Marshall's is forgotten.

There has always been a source of regret to me—as it must be to all alumni of University College—that Lister's work was not carried out at his old school. But the fates have ordained otherwise, and to Glasgow and Edinburgh must be conceded the credit of nursing the new surgery into glorious existence. I believe it would have made a great difference in the rapidity of the spread of the new doctrine if they had emanated from London, and Lister, no doubt, thought so himself, as his subsequent migration to London showed. The atmosphere of University College—if it was in 1866 that he applied for the appointment—less than a year after he had started his experiments on antiseptics in Glasgow. According to my own time. And if I have wondered what a difference would have meant to me, a mere physiologist, to have had a surgical training under Lister, how much greater would have been the difference to Victor Horsley if he had come under the direct influence of this great scientific surgeon. He would have been Lister's house-surgeon instead of Marshall's, and how enormously he would have benefited by the close relationship with Lister, and how keenly would have followed and assisted in his experiments, and whose memory we are assembled to-day to commemorate, and whose loss not only to physiology and surgery, but to the whole world, will be felt for many a year.

Dividends and interest show an increase of £67 odd this year. The donations include the legacy of £2,000 left by the late Mr. Musgrave of Belfast, which has been invested, and £200 from the Carmichael Fund, also a donation of £10 from Dr. C. Holmes Denham, who has been elected as a life member. The revenue from all sources for the year, including the donations, is £3,549. The actual subscriptions show a decrease of £53 odd, being £540 as compared with £593 last year. The greater part of this decrease represents subscriptions from the various Dublin hospital students not received in time for audit. There is also a further amount of £277 income tax refund still outstanding.

#### *Work of the Irish Benevolent Fund.*

The Committee draws special attention to the amount of grants disbursed during the year—namely, £1,695 as compared with £1,215 last year, an increase of almost £500. The Osborne account shows a debit balance of £207, which has been advanced from the General Fund. The Committee thanks the British Medical Association for receiving subscriptions for this Fund amounting to £25 13s. 6d. The Central Committee places the following facts before its non-subscribing colleagues:

That the Society is a purely Irish one, administered by Irish medical men for the benefit of the widows and orphans of Irish medical men who have practised in the country. That the Central Committee in allotting grants rely upon the recommendation of the various honorary secretaries and subscribing colleagues who have local knowledge of each case, and the amount of relief given entirely depends upon the needs of the applicant and the available funds. That help given to those in distress is given promptly and is as much as the resources of the Society permit. That the number of non-subscribers receiving benefits amounts to 40 as compared with 41 subscribers. That the Central Committee have this year given £500 more than last year in grants on account of the great distress due to higher cost of living, that the bank balance at the moment is only £888 12s. 1d., and that even to continue the work next year £1,200 must be raised or the relief must stop.

The Central Committee appeal most earnestly to their non-subscribing colleagues throughout Ireland to consider the claims that this charity has upon them and to help by an annual subscription, however small. Seventy-five per cent. of the medical profession, in spite of appeals, does not subscribe, and so leaves the charity dependent upon the generosity of their colleagues, past and present. There are over 3,000 practitioners in Ireland, and 10s. from each would place this Society on a sound financial basis, and would so enlarge the grants allotted that relief to the distressed would be possible.

The report shows that the medical practitioners in Belfast and Dublin have, apart from their advantage in numbers, been the most liberal subscribers to the fund. The medical practitioners in the cities of Cork and Limerick have also done very well. Wexford has done the best of the counties; this county, in the matter of public subscriptions for medical objects, is indeed an example to all the boroughs and counties in Ireland. The grants from the fund are almost entirely made to the widows and orphans of the medical men who served in the Irish Poor Law medical services. This fact should, in many cases, be more generally appreciated by Poor Law doctors than is the case.

#### *PRESENTATION TO A DISPENSARY DOCTOR.*

On October 3rd, at Bannfield, Coleraine, Dr. J. T. Creery, medical officer of the Coleraine dispensary district, and medical officer of health for the urban district, was presented by his numerous friends with a new motor car, fitted with every convenience, as a recognition of his life-long services to the community, and their gratitude for his unwearying labours and high professional skill, ever available for both rich and poor. Dr. H. S. Morrison, D.L., M.P., bore testimony on behalf of the medical profession to the high esteem in which Dr. Creery was held in their ranks, and to the gladness with which they joined in doing honour to one who had done so much for others. Dr. Creery has been medical officer in Coleraine for over forty years.

## England and Wales.

### *HEALTH PROPAGANDA IN YORKSHIRE.*

IN connexion with the health propaganda that was carried on throughout the country during "National Health Week," from October 7th to 13th, a joint committee was appointed by the County Council and the Insurance Committee of the West Riding of Yorkshire. This, under the direction of the medical officer of health, Dr. J. R. Kaye, was very successful in bringing together in prominent association the curative and preventive sides of medicine. Addresses were delivered to school children by 142 medical practitioners in the West Riding, and where it was impossible for a medical practitioner to give an address it was delivered by the head master of the school. Outline notes for such an address were printed and circularized to those concerned, and "health cards" were distributed to the school children at the conclusion of the addresses, one being a scholar's "health creed" and the other an acrostic on the Health Week motto, "Self-help in health." Over 214,000 of these cards were distributed. Nearly 2,000 circular letters were also sent out to all clergy and ministers of religion in the West Riding, asking that in the course of the sermon to be preached on the Sunday of the week some reference should be made to the subject of health.

### *ANNUAL MEDICAL SERVICE IN LIVERPOOL.*

The Bishop of Manchester, Dr. W. Temple, preached the sermon at the annual medical service at St. Luke's Church, Liverpool, on October 14th, before a large congregation. The Lord Mayor and Lady Mayoress attended in state, and the vice-chancellor of the University, Dr. Adami, and many medical men of the city and neighbouring districts in academic robes, were present. The service was conducted by the vicar of St. Luke's, and the lesson was read by the archdeacon. The sermon was based on the meaning of life and the mystery of evil. Four strata might be distinguished, he said—matter, life, mind, and spirit—and these were all correlated. Each stratum required the one above it to reveal and develop its own possibilities, while each of the higher strata needed the lower ones to enable it to exist at all. Evil was merely evil until it had been made the occasion for the moral victory that triumphed over it, and then it became an element in good. The meaning of life was the continual progressive victory of the higher over the lower elements. The healing of men's bodies and the healing of men's souls could not be separated. More and more were we learning how interdependent they were. In devoting itself to the healing art the medical profession was an example to most of those who served in other ways. Through self-forgetfulness and self-dedication the conflict with evil in all its forms rendered man a partaker of the divine nature and co-operator in the activity of God. The offertory was made on behalf of the Royal Medical Benevolent Fund, and amounted to £51 4s. 4d. The honorary treasurer, Dr. J. Ernest Nevins, 32, Princes Avenue, Liverpool, would gratefully acknowledge any further donations from those who were unable to be present at the service.

A new sterilization law was passed by the last session of the legislature of the State of Oregon, U.S.A., setting up a State board of eugenics, comprising the State board of health and the superintendents of the two State hospitals for mental disease, the State institution for the feeble-minded, and the State penitentiary. The superintendents of these institutions are required to report to the board quarterly the cases of all persons who are feeble-minded, insane, epileptic, habitual criminals, moral degenerates, and sexual perverts who are likely to become a menace to society. If, in the opinion of the board, the condition of the person is unlikely to improve and procreation would produce children with inherited insane, epileptic, criminal, or degenerate tendencies, the board shall specify the type of sterilization to be performed; the person may select his own surgeon, subject to the approval of the board.

bowel also causes an inflammation of the appendix, which is frequently anchored and obstructed by acquired adhesions of the meniscus membrane of the colon, producing colitis in its various degrees and forms. The appendix is often so secured as to control the local elements and to increase the stagnation of the material in the small intestine.

#### Its Toxicemic Results.

Besides these mechanical results of stasis, the sequence of which is quite obvious, we have those which are consequent on the fouling by organisms of the dammed-up contents of the small intestine of the duodenum, and even of the stomach, with the extension of the infection along the hepatic and pancreatic ducts which produces gall stones and cancer. The mode of extension of the infection in these is as apparent as the mechanical changes.

The next series of changes we have to consider are those which come about by the absorption from the infected contents of the gastro-intestinal tract of more toxins, etc., than the liver is able to deal with. These noxious substances getting into the circulation are carried to every organ and tissue in the body and produce disastrous results in proportion to the degree of the toxicity of the blood.

The degenerative changes in the thyroid, adrenal, and other ductless glands, the heart and blood vessels, the nervous system, the eyes and ears, the kidneys, liver, pancreas, uterus, testes, prostate, breasts, larynx, and hair lymphatic tissue of the naso-pharynx, and the gums and teeth—these two last being the most frequent and conspicuous of all—I have frequently described in detail, and I have shown how liable certain of these degenerated organs, such as the breast, uterus, ovary, and pancreas, are to be infected with cancer.

Among the nervous symptoms may be mentioned intense headache, neuritis, neuralgia, sleeplessness, misery, complete mental and physical prostration, melanolia, epilepsy, disseminated sclerosis, delusions, and dementia.

Besides these changes, which are the direct result of the supply of toxic blood to the tissues, we have a number of infections which occur because of the inability of the degenerated tissue to withstand their intruders. These infections are all of such a nature as to be unable to obtain a foothold in a normal healthy subject.

#### CANCER NEVER AFFECTS A HEALTHY ORGAN.

Perhaps the most conspicuous at the present moment is cancer. In every case in which I have had an opportunity of verifying it I have found that the cancer patient was suffering from chronic intestinal stasis and that the infection by cancer was an indirect consequence of this condition.

If this assumption is correct it is obvious that to prevent the development of cancer it is necessary to obviate these changes which result in the gastro-intestinal tract from the diet and habits of civilization. That an enormous amount of benefit and a corresponding freedom from cancer has been obtained by the use of paraffin is in my opinion undoubted. I ventured to employ paraffin when I recognized the mechanics of chronic intestinal stasis, and have used it in every case of chronic intestinal stasis, and unnecessary to operate on all patients suffering from this disability. Its usefulness is also confirmed by the extraordinary manner in which it has spread over the whole world. I doubt whether any other material or drug has ever given anything like the same comfort and security from disease that it has. By its use the irritation and harm which result from the action of a purgative are avoided, while it acts on the principle of the flushing tank, rendering the motion soft and ensuring two or three free actions a day.

The other diseases that affect the subjects of chronic intestinal stasis are rheumatoid arthritis, Still's disease, tubercle, Raynaud's disease, many splenic affections, ulcerative colitis, many skin diseases, diabetes, ulcerative endocarditis, gout, etc.

How is this to be done? It can only be effected by a complete revolution in our diet and in our habits of life. We must assimilate them to those of the natives, among whom the entire stasis sequence is unknown. How this can be done with as little sacrifice of the pleasures of the table must be investigated by dietetic experts, to whom the problem should not present insuperable difficulties. It must necessarily be a compromise, but the more thoroughly we approach the conditions of primitive life the more successful shall we be in avoiding the incidence of a very great number of diseases.

Roughly, it would seem that the diet should consist as much as possible of vegetable matter, that it should be consumed largely in a raw state, to avoid damage to vitamins, that coarse indigestible material be retained in order to increase the bulk of the intestinal contents and their stimulating action on the reflexes, that food which it kept becomes offensive and poisonous should be eliminated as much as possible, and that the consistence of the faeces be diminished, and the frequency of their evacuation increased.

#### Simple Operative Treatment.

So much for the prevention of stasis. As to the treatment of the existing condition apart from medical treatment by a Curtis belt, paraffin of high viscosity, kaelin, and abdominal exercises, all operative measures on any portion of the gastro-intestinal tract should be started by an examination of the last link, and by the careful freeing of this bowel from its acquired attachment to the iliac fossa. This requires to be done thoroughly, and when the mesentery has been restored to its normal length and the bowel to its normal freedom any raw surfaces of mesentery must be accurately covered by peritoneum to obviate any recurrence.

Perhaps of all operations in surgery this procedure alone is followed by the most wonderful effect. The whole condition of the patient is transformed and he is rapidly restored to vigorous health. After all this is not surprising, since it is because of this obstruction that all the other changes in the gastro-intestinal tract, whether mechanical or toxic, ensue.

To my surprise I have on very many occasions secured the same advantage by this simple operation that I have previously obtained by colostomy at a considerably greater risk. Because of the remarkable results which can be obtained by this procedure I am anxious that its value should become recognized.

Having dealt with the last link the colon should be examined to make sure that no secondary constriction has developed, and particularly in the region of the splenic flexure. Any acquired band found controlling the lumen of the bowel should be divided carefully, avoiding leaving any raw surfaces deprived of peritoneum. An indomitable and untiring appendix in an ideal link should be looked for, and dealt with if present.

I do not propose to discuss the surgery of ulcer of the duodenum and stomach, but I would like to state that the disappearance very rapidly after this simple procedure. I hesitate to say what I believe to be the cases of its effect upon duodenal and gastric ulcers will I have been able to contain my views by a much larger experience, but I am convinced that the employment of the common-sense measures I adopt will reduce very materially the frequency and severity of operations on the upper portion of the gastro-intestinal tract, and will free the sufferer from a large number of the consequences which ensue directly and indirectly from chronic intestinal stasis and from the auto-intoxication which results from it.

#### PREVENTION OF STASIS.

Our chief interest at the present time is to prevent the development of chronic intestinal stasis and so to obviate the development of the several conditions which are due directly or indirectly to its presence, of which latter group cancer interests the public particularly because of its frightful mortality and the physical and mental anguish so frequently associated with it.

that so commonly used by the patients we operated on, and who were for the most part not strict vegetarians.

It is practically impossible in the case of a village population, such as one has to deal with in India, to frame anything like accurate statistics. The majority of the patients are not seen again after they leave hospital, but quite a number were seen three to five years after operation, still in good health.

I am glad to record that I saw two cases upon which Mr. Fells had operated for cancer of the lower jaw, the one nineteen, the other eleven years previously. Both were quite free from disease. I also saw a case of total excision of the tongue for cancer, done by the same surgeon eighteen years previously, with no sign of recurrence of disease.—I am, etc.,

Sellhurst, S.E.25, Oct. 15th.

JAMES DAVIDSON.

SIR,—Similar experience in Travancore to that of Mr. R. L. Spittel in Colombo leads me to corroborate entirely his description and conclusions. The habits of Travancoreans in the matter of betel chewing evidently agree very closely with those of the people of Ceylon, the usual quid consisting primarily of a betel leaf smeared with lime with in most cases some country dried tobacco and a fragment or two of areca nut. The use of the lime-smeared leaf begins commonly in youth, the tobacco being often, I fancy, a little later addition, the habit becoming eventually one almost impossible to be broken, even when its dire local effects begin to be noticed.

Having recently left India after twenty-one years' charge of the Salvation Army hospitals in Travancore I cannot now refer to actual records and statistics, but at the Catherine Booth Hospital of 72 beds in Nagercoil we practically always had a case or two in, and I have sometimes operated on three or four in a week, after having to turn away others as too far advanced even to render justifiable a merely palliative removal to get rid of a foul, painful mass rendering food-taking difficult and life almost insupportable.

As Mr. Spittel says, the almost invariable beginning is leucoplakia of the cheek opposite the molars and pre-molars, and I think more frequently on the left side, which I have noticed to be the more favoured side in practice for the keeping of the quid; the actual growth commences usually at or behind the centre of the leucoplakial patch, so that one may find this appearance reaching practically to the angle of the mouth or further, perhaps an inch in front of the epitheliomatous lump. I should say that the common age at which patients presented themselves was in the late forties and the fifties, but I have seen it in a woman as young as 35, and I think once a little younger. Once formed, the growth tends to spread centrifugally, generally reaching the lower sulcus and then the gum and alveolar process before the upper, and spreading forwards, I think, more rapidly than backwards. After a time it burrows towards the skin surface, finally going on to involve the skin.

The glands are not noticeably involved very early, the first palpable being discrete and mobile, and perhaps due rather to the septic state of the mouth with the frequently coexistent pyorrhoea and tartar, than to commencing secondary epitheliomatous involvement (which, however, surely follows), the first gland notable to palpation being generally situated under the edge of the jaw, beneath the first molar tooth. At a later stage gland involvement below the mastoid process appears and this sign has come to mean to me the absolute bar to any attempt at removal, appearing particularly to go with deep involvement of the pterygoid region, rendering even an apparently clear margin out of the question.

Recurrence generally occurs far back or else along the line of healing on the buccal surface. In cases where, the jaw having been affected, the cheek growth, half-jaw and glands beneath have all been removed *en masse*, further glandular involvement is not usual, but in one or two cases where the extremely local character of the cheek growth and the absence of any palpable glands have led me to leave the neck alone, I have seen very rapid involvement of the neck glands, far surpassing in rapidity and amount the

usual course with a primary growth *in situ*, as if, perhaps, the combined influence of the cancer cells absorbed before or liberated at the time of operation and the absorption of inflammatory products from the healing mouth wound produced a far greater effect than either would have done separately.

In cases where the primary growth seems local and removable I have come to favour strongly the method that I see Mr. H. J. Paterson suggested in general at the Section of Surgery at the Annual Meeting, and has practised in particular on a series of cases of cancer of the tongue—namely, to remove the primary growth first and the glands some weeks later, after they have had time to “intercept any cancer cells left behind in the wound, acting indeed as Nature's wound scavengers” (September 29th, p. 557).

I do not think that Dr. John Campbell's theory of infection “by a hand contaminated by soil” is at all borne out by the probabilities of the class of cases we are considering, in which event cases should be far more numerous both in gross and in proportion amongst those who labour on the land; I should say that, if anything, more cases, both numerically and certainly proportionally, would be found among the non-agriculturists, who, having more leisure and money, in many cases chew the more. Cases, for instance, are quite common amongst the Brahmans, who neither sow nor reap in the agricultural sense.

In conclusion I may say that while cases of this form of cancer are common amongst chewers of betel, there is in Travancore, and I suppose in Ceylon, a minority of people who do not chew: I have never seen a case of the kind in a non-chewer.—I am, etc.,

London, N.19, Oct. 15th.

PERCY E. TURNER, M.D., B.S.

#### THE TREATMENT OF TUBERCULOSIS BY THE SPAHLINGER METHOD.

SIR,—I am greatly indebted to Dr. Watts (October 13th, p. 680) for supplying additional facts concerning M. Spahlinger and his method of treatment; but the point is, why has not M. Spahlinger placed his discoveries before the medical and scientific world?

Dr. Watts states that there is no secrecy about the preparation of the serums and vaccines, yet this statement is at variance with the report of the Chief Medical Officer to the Ministry of Health. This report affirms that the technique adopted in the preparation of the serums and vaccines remains undisclosed, and goes on to say that an offer was unofficially made to M. Spahlinger for a medical committee to investigate his method of treatment, but he was unable to accept this offer in spite of the fact that he would not be required to divulge his technique of preparation.

Why did not M. Spahlinger accept this offer, especially as he had 400 cases already treated?

I do not think the medical profession is prejudiced against him just because he is not a medical man. It is because he fails to disclose his technique, and if his treatment is all that he claims for it then it is his duty to suffering humanity to place that technique before the profession. Moreover, if his financial situation is such that he cannot proceed with the preparation of his serums and vaccines why has he refused offers of several hundred thousand pounds, just to reserve to himself the exclusive rights of this method of treatment?

I think the Ministry of Health acted very fairly towards M. Spahlinger, and it does not redound to his credit that he did not avail himself of the opportunity then placed before him of demonstrating the efficacy of his method of treatment, or on the other hand of supplying the information necessary for the proper preparation of the vaccine by bacteriologists more favourably situated than himself. Could he not be induced to publish his technique? It would not detract one iota from his reputation, for in all probability his name would always be associated with this method of treatment, and should the results be successful so much the more would he be esteemed.—I am, etc.,

GEORGE W. CHEATER, M.B., D.P.H.

Whipps Cross, E.17, Oct. 15th.

who lived in Dovedale, was a fishing friend of Izaak Walton. He leaves five children. His eldest son is Sir Michael Sadler, Master of University College, Oxford, and his second, Dr. F. J. Sadler of Barnsley.

The death is announced at Marley, Garmouth, Morayshire, of Dr. WILLIAM GEDDIE, who was for forty-four years a well known medical practitioner at Accrington, Lancashire. He received his medical education at the University of Aberdeen, and graduated M.B., C.M. in 1874 and M.D. in 1886. After a brief period in Rossendale he went to Accrington, where he speedily established an extensive general practice. Devoted to his profession, Dr. Geddie was recognized as a most able practitioner, and the greatest confidence was reposed in him. He held many public appointments, and for more than twenty-five years was police surgeon for the borough. He was a member of the honorary medical staff of the Victoria Hospital, Accrington, from its foundation in 1896, and on his retirement from the active staff he was appointed consulting surgeon. During the war he acted as medical officer to Baxenden Red Cross Hospital. He was an old member of the British Medical Association. Dr. Geddie was twice married, and is survived by his widow and by four sons, two of whom are members of the medical profession.

Dr. JOHN LYELL SMIRTHWAITE-BLACK, who died at Burnley on September 20th, was a native of Fife, and received his medical education at the University of Edinburgh, where he graduated M.B., C.M. in 1881. His father, the late Dr. Black, was a medical practitioner in Burnley, who died in 1886, and the name of Smirthwaite was assumed by Dr. Smirthwaite-Black when he married the widow of the late Dr. Smirthwaite in 1889. He was a member of the Burnley Borough Council for over fourteen years from 1889, but otherwise took little part in public life. He had a cultivated taste in literature, and was devoted to his hobby of rose-growing. He is survived by his widow.

Dr. HAROLD MOWAT, radiologist to the Government of the Federated Malay States, died at Kuala Lumpur, the capital of those States, on August 21st, aged 40. He was educated at Manchester and Edinburgh Universities, and graduated in the latter as M.B. and Ch.B. in 1905, and as M.D. in 1907. After acting as house-surgeon of the Royal Surrey County Hospital at Guildford he took up radiology as a specialty, and had filled the posts of clinical assistant in the x-ray and electricity departments at Charing Cross Hospital, medical officer in charge of the same departments at the Metropolitan Hospital, and radiologist of the Royal Chest Hospital in City Road, London, and of the Hampstead and North-West London Hospital. He took a temporary commission in the R.A.M.C. on November 2nd, 1914, and served as radiologist in No. 17 General Hospital and in No. 12 Indian General Hospital, and also served for some time as surgeon in the Royal Navy. He had only recently taken up his late post.

## The Services.

### TERRITORIAL DECORATIONS.

THE Territorial Decoration has been conferred upon the following officers of the R.A.M.C. (T.A.) under the terms of the Royal Warrant dated October 13th, 1920: Colonel P. B. Giles, C.B., F.R.C.S., V.D. (ret.); Lieut.-Colonel F. Darlow, Major H. Henry, M.C., and Major J. E. N. Ryan.

### DEATHS IN THE SERVICES.

Surgeon Colonel William Thomas Martin, Army Medical Staff (ret.), died at Bournemouth on September 15th, aged 81. He was educated at Queen's College, Galway, where he graduated B.A., gaining the gold medal, in 1859, and M.D. in 1862, both being degrees of the late Queen's University; he took also the L.R.C.S.I. in the latter year. In 1882 he graduated M.A. of the Royal University of Ireland, which had taken the place of the Queen's, and in 1920 received the degrees of M.A. and M.D., *ad eundem*, from Belfast University. He entered the army as assistant surgeon

in 1863, and served under the old regimental system in the 45th Foot, now the No. 10 and Derby Regiment, or Sherwood Foresters. He attained the rank of surgeon colonel on June 6th, 1893, and retired on September 2nd, 1896. He served in the Abyssinian war of 1867-68, when he was present at the capture of Magdala, was mentioned in dispatches in the *London Gazette* of June 30th, 1868, and received the medal; and in the Burma war from 1885 to 1887, receiving the Indian Frontier medal with a clasp. In 1876-77 he was surgeon to the Governor of Madras, and afterwards, in 1880-82, was on the staff of the Royal Victoria Hospital and Army Medical School, Netley.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

Degree Days.—The remaining degree days in the present term are: Thursday, November 1st, Saturday, November 17th, Thursday, November 29th, and Saturday, December 15th.

### UNIVERSITY OF CAMBRIDGE.

At a congregation held on October 13th the following medical degrees were conferred:

M.D.—W. F. R. Castle, H. A. Williams.  
M.B., B.Ch.—W. G. Woolrich.  
M.B.—A. B. Bratton, E. C. Curwen.  
B.Ch.—F. E. Higgins, S. Orchard.

### UNIVERSITY OF GLASGOW.

The following degrees were conferred on October 15th:

M.D.—J. N. Cruickshank, \*D. M'Alpine (in absentia), H. M. C. Lang, Alexandra M. MacLennan, C. L. Sutherland, W. Telfer, K. Falconer, A. Fraser, H. J. Macbride.  
M.B., Ch.B.—B. G. Ives, \*D. L. Pow, \*A. S. Henderson, A. Meiklejohn, Janet M'Le Stewart, A. M. Girvan, M. Cohen, J. M. Henderson, J. M. K. Fleming, P. Shannon, Monica M. Bateman, J. Gibb, T. W. Hill, A. M'Leellan, J. H. Adam, J. R. B. Alexander, S. M. Allan, C. P. Allan, Isabella D. Anderson, M. C. Bain, Margaret A. Barr, O. F. Barr, H. Baxter, J. B. Bell, J. S. Bizzett, J. D. Black, R. Black, C. C. Blair, H. W. Bowyer, Marion C. Boyd, W. Brown (Ardrossan), W. Brown (Glasgow), W. M. Brown, A. Browning, T. W. Buchan, I. M. Burdon, A. B. Burns, J. B. Bushe, Isabella E. Campbell, P. A. Carrie, Evelyn L. Caskey, D. L. Charters, Isobel M. Chisholm, G. Cochran, S. R. Costley, V. Craig, G. M. Currie, Lucie Leon van Dam, A. F. Davidson, Elsie B. Dickinson, J. L. J. Fleming, Anne M. Forrest, J. C. J. Braith, E. J. M. Gallagher, J. E. Geddes, J. S. Gilbert, J. D. Glaister, A. D. Gowans, Mary J. L. Gracie, G. F. Graham, J. W. Graham, Christina Grant, R. Haddock, A. Hamilton, J. Hamilton, W. Hay, D. Henderson, J. Henderson, N. P. Henderson, E. Holmes, W. A. Horne, Jennie C. Hunter, T. M. Hunter, Sara Jacobs, R. J. Jarvie, D. P. K. Jockel, M. Joels, J. M. Johnston, J. S. Kamester, W. Kelm, J. A. Kerr, M. Laidlaw, J. Laurie, Agnes A. Lawson, J. C. Lindsay, Flora Livingstone (Mrs. R. N. MacDonald), A. Logan, M. A. Logan, Daisy B. M'Brice, Alexandra M. MacCormick, Agnes M'Creddie, H. M'Crorie, A. W. M'Curloch, Eileen M. M. MacDonald, Isobel C. MacDonald, S. R. M'Dougall, A. M'Glashan, Cecilia M'Guinness, D. G. S. Mackay, Mary L. M'Kay, T. S. M'Keen, Euphemia D. Mackenzie, J. C. H. M'Kenzie, P. L. M'Kinlay, W. W. Mackinlay, J. M'Learen, Margaret B. M'Leellan, A. M. Macleod, Catherine M. Macleod, M. Macleod, N. Macleod, N. C. Macleod, Grace M'Lintock, Margaret J. M'Pherson, May Marshall, Margaret M. U. Martin, R. D. Martin, E. E. Miller, D. M. Mitchell, J. J. Mitchell, Marjorie H. Mitchell, G. Montgomery, A. Morrick, Leah Morris, J. G. Munro, M. Murchison, T. J. Murray, R. Naftalin, Gertrude M. Neale, T. C. H. Neil, J. Ordansky, M. Orr, G. A. Pollock, T. G. Rankine, L. Reid, Margaret G. Reid, Annabella Rennie, J. Kennie, S. Rowles, Kathleen M. Riddle, H. Rinn, D. Robertson, W. M. Robertson, Florentina M. Robinson, Alice Rosenblatt, A. W. Ross, A. Russell, Georgina Russell, J. M. Seaton, A. C. Scott, S. C. Scouller, N. S. Sotton, W. C. Sharp, H. J. Sheppard, A. Sheridan, J. S. T. Skottow, C. C. I. Slorach, R. McD. Smellie, Elizabeth C. Smith, M. A. Mary S. Smith, Olive M. Somerville, S. M. Steel, E. G. Stevenson, L. Stevenson, Mary Y. M. A. Stevenson, W. L. Stewart, Margaret E. Stobo, A. J. Struthers, G. Struthers, Nora Surtees, A. Sutherland, W. D. Sutherland, W. S. Syme, Annie V. Taylor, W. M. P. Taylor, T. Tennent, D. F. S. Thomson, Ann W. Turnbull, A. B. Waddell, Thomson, M. L. M. Thomson, J. A. Waterman, J. N. Watson, J. Walker, R. Walker, H. C. Wallace, J. A. Waterman, J. N. Watson, W. H. Watson, W. T. Westwood, J. Wilkie, Anne C. Wilson, H. E. C. Wilson, W. B. Wilson, J. Wingate, Margaret E. Wyllie, J. S. Young, Jean L. Young.

John Stirling Young, M.A., B.Sc., M.B., Ch.B., who graduated on April 21st, 1923, gains the Brunton Memorial Prize of £10, awarded to the most distinguished graduate in medicine of the year.

\* With honours.

† With commendation.

### UNIVERSITY OF ST. ANDREWS.

DURING the ceremonies connected with the installation of Mr. Rudyard Kipling as Lord Rector of St. Andrews University last week the honorary degree of LL.D. was conferred upon Sir John Bland-Sutton, President of the Royal College of Surgeons of England, and consulting surgeon to the Middlesex Hospital.

At the graduation ceremony held on October 5th the Vice-Chancellor, Principal Irvine, inducted Professor Adam Patrick to the Chair of Medicine, and Professor John Read to the Chair of Chemistry. The following medical degrees were conferred:

M.B., Ch.B.—M. K. Afidi, C. B. Baxter, T. F. Black, N. T. B. W. F. Dorward, E. Douglas, A. A. Finnigan, J. R. Graham, L. Johnston, J. A. G. Keddie, G. D. Laing, J. P. Laird, F. M'Lagan, J. R. Murray, N. Nelson, P. C. Robertson, J. O. Stephen, G. J. Sturrock.

# THE REGULATING AND REFLEX PROCESS.

85

P. T. HERRING, M.D.,  
 PROFESSOR OF PHYSIOLOGY, ST. ANDREW'S UNIVERSITY, AND  
 PHYSIOLOGIST TO THE ST. ANDREW'S HOSPITAL FOR  
 CLINICAL RESEARCH.

## PART IV.—NERVE CENTRES: THEIR CONSTITUTION AND SIGNIFICANCE.

The term "nerve centre" is applied to a collection of nerve cells in the central nervous system which are associated together in the performance of some particular function. The term is a very elastic one and is used to denote a number of different conceptions. Its very elasticity makes its use convenient, but the term lacks precision and is apt to obscure the conditions which really exist. The nerve cell is only a part of the neurone, and the nerve impulse, may extend to great distances from the cell body. The term ascribes to the cell body of the neurone an importance which the facts do not warrant.

A collection of nerve cells—the cytons or cell bodies of the neurones, which give origin to an efferent nerve—is known anatomically as the nucleus of the nerve. It may also be termed an efferent nerve centre, and the neurones of which it is composed carry nerve impulses from the anatomical nucleus of the efferent nerve presents an important difference. It also lies in the central nervous system, but its cytons do not give origin to the peripheral axons. The cells of origin of the efferent neurones are found in the ganglia of the posterior nerve roots of the spinal cord and in the corresponding cranial ganglia. The impulses they receive at the periphery are carried into synapses before they reach the neurones of the efferent centre, and are therefore liable to all those influences which the synapse is capable of exercising.

The efferent neurones not only innervate certain structures in the periphery but also exert some kind of nutritive influence over them. If they supply voluntary muscle, that muscle fails to develop properly if the efferent neurone does not also develop, and injury to the neurone or centre of a retrogressive nature. The efferent centre, on the other hand, is separated from the peripheral afferent neurone by an irreproducible synapse, and is therefore unable to exercise any control over the peripheral neurone. Injury to the afferent centre may leave the peripheral neurone intact and able to maintain the nutritive functions it possesses by its axon reflexes.

Anatomically, therefore, there may be an afferent or receiving centre and an efferent or distributing centre in a reflex arc. But the reflex does not necessarily require either of them, the axon reflex being an example. In cases there may be no afferent centre. There is evidence that in a deep tendon reflex, such as the knee-jerk, the afferent nerve impulse is conveyed directly to the peripheral efferent neurone, and there is only one synapse in the reflex arc. In the majority of reflex arcs more than two neurones are concerned, and consequently an example of a nerve centre in which there are many neurones concerned is furnished by the cerebellum. The cerebellum is essentially an afferent centre which receives nerve impulses from proprioceptors in the body. The nerve impulses have passed through at least one synapse before reaching the cerebellum, a fact of very great importance, because opportunity is thereby afforded for the spread of the impulse to other pathways, with the resulting production of pain and other phenomena. The afferent centre in the cerebellum is in turn able to excite

\* The expense of this research was in part met by a contribution from the Medical Research Council.

efferent neurones, the cells of Purkinje, which distribute the impulses to efferent neurones in other parts of the nervous system. The reflex through the cerebellar arc is therefore an example of one in which there are a number of neurones and synapses concerned. Reflexes through the cerebrum appear to be carried over even more complex arcs, and the possibilities of spread of the nerve impulse, and of its inhibition or diversion into other pathways, is correspondingly greater.

Physiologists employ the term "nerve centre" to denote collections of nerve cells in the central nervous system which are associated with the co-ordination of some definite physiological function. The anatomical units of which they are constituted are not always definitely located, and in some cases the centres are assumed to be present in certain positions although their very existence may be hypothetical. The heat-regulating centre is said to exist in the corpus striatum, and to control the nervous processes which regulate the production and loss of heat by the body. The centre is supposed to be directly influenced by the temperature of the blood in the blood vessels in its vicinity. If such action does occur it is unlikely that the body of the nerve cell in the centre is the site of stimulation by the change of temperature. It is possible that there are in it special receptors which are stimulated by changes in temperature, but far more likely that the synapses are the parts affected. To say that the centre is controlled by the temperature of the blood circulating through it is no explanation of where and how the action takes place. Variation in the resistances of the synapses in the centre as the result of changes in temperature afford a working explanation.

The same ambiguity attaches itself to other centres which are supposed to be the sites of a direct action by outside agencies. The respiratory centre is in some way influenced by the concentration of the hydrogen ion in its vicinity. The part stimulated by the hydrogen ion may be, as implied by Haldane, special receptors in the dendrons of cells in the centre, but it appears to us to be more likely that the hydrogen ion affects the resistances of the synapses in such a way that the afferent impulses are differently distributed and thus lead to alterations in the nerve impulses which leave the centre along the efferent neurones. The respiratory centre is generally considered to possess the power of automatism and to be the site of rhythmic discharges of nerve impulses. This automatism, if ever present, disappears during the condition of apnoea induced by the artificial diminution of the hydrogen ion concentration of the blood. It is never stated in what part of the respiratory centre the power of automatism resides. When one attempts to analyse the respiratory centre many difficulties are met with. The centre has been roughly located by physiological experiments in an area in the medulla oblongata in the neighbourhood of the afferent nucleus of the vagus nerve. Afferent nerve impulses are carried to it by the pulmonary branches of the vagus and give rise to the Hering-Breuer reflex. Afferent nerve impulses are also carried to it from numerous other sources, but whether they all go to the afferent nucleus of the vagus or to other neurones on the efferent side is unknown. The position, too, of the special receptors, if such exist, is not known. The synapses on the afferent side of the centre must be capable of alternation between excitation and inhibition, and of varying degrees of resistance to the passage of nerve impulses.

Provision is made for reciprocal innervation. The afferent impulses, whether from the pulmonary fibres of the vagus or from the afferent fibres of the nerves supplying the muscles of respiration, must inhibit certain neurones and excite others so as to bring about a proper co-ordination of the efferent nerve impulses to the muscles of respiration and expiration respectively. The terminal efferent neurones leave the central nervous system at various levels according to the muscles they supply, and their cells of origin are found at considerable distances from the actual centre. The centre is also similarly controlled by nerve

## INCOME TAX.

### *A Groom-Gardener.*

"H. M. C.'s" groom does odd jobs about the place and works on a ten acre holding, in addition to doing work in connexion with the practice. The inspector of taxes wants to know what proportion of his wages is paid for the latter.

\* \* The inspector is within his rights in claiming to restrict the deduction made for purposes of the Schedule D return to the proper proportion. In the absence of any definite criterion, the proportion might be reckoned by reference to the time spent by the groom on work for the practice, as compared with his other work. Something might reasonably be added to that estimate on the ground that his work as groom was his primary job, and that the other work was done to fill up his time.

### *Hospital Residents.*

"L. D." holds a resident hospital appointment, which was advertised as of the value of £125 per annum plus board, rooms, attendance, and laundry. In fact he receives the salary plus an allowance of £6 10s. a month for board and 3s. a week for laundry, and is charged by the hospital with an account for board and lodging. Is he liable to assessment in respect of anything beyond the £125 per annum?

\* \* The leading case on the subject is *Tennant v. Smith*, in which the House of Lords laid down the rule that income tax does not extend to anything which is not received in money or in a form capable of being turned into money. This rule draws a clear but not very equitable distinction between, for instance, a salary to an outdoor employee, which is entirely assessable to tax, and a smaller sum paid in regard of the fact that the recipient has certain advantages (not capable of being turned into money) such as free board or residence. "L. D.'s" position is somewhat peculiar and it is not easy to say into which category his allowances fall. There appears to be no judicial decision covering the point, which is whether the crediting of his account with the allowances, coupled with the condition that that account is liable to the charge for board, etc., amounts to a payment in money. There are two weaknesses in his contention—first, that he is entitled to draw out at least the unexpended portion for private purposes, and secondly, that equity is against him: the real worth of his emoluments is represented by the total, and the ordinary salaried employee pays on that basis.

### *The Car of a Retiring Practitioner.*

"J. F." has recently given up practice and expects to lose, say, £250 when he disposes of the car which he formerly used for professional purposes.

\* \* "J. F." cannot claim any allowance in respect of the loss; the only sum that can be allowed is the expense of replacement, and the car is not being replaced; further, as "J. F." is not now in practice, he is not paying tax on professional income and there is no assessment from which a deduction could be made. This case illustrates the unfairness of refusing professional earners permission to deal with the expense of maintaining their cars by a deduction for annual depreciation; where replacement cost is the basis of the allowance there must always be an ultimate loss to the taxpayer. The Royal Commission on the Income Tax recommended that a change should be made, but it is a long time in coming.

## LETTERS, NOTES, ETC.

### HOMES FOR MENTAL CASES.

DR. A. C. GEMMELL (Brighton) writes: In the *BRITISH MEDICAL JOURNAL*, August 4th (p. 214), you deal with the question of certifiable but uncertified lunatics in nursing homes. I am clear that a lunatic cannot legally be kept for profit in a nursing home except under certificate; I am also clear that such a patient can legally be kept without certificate in the house of his parents, where there is no question of payment; but I am in doubt about the intermediate cases. For instance, can a lunatic not under certificate be received into furnished rooms, the son of the lunatic paying for the lunatic's board and lodging and also for the services of a nurse provided by himself? If this is legally possible, what is the distinction in principle between the boarding house and the nursing home? If this is illegal, it places a heavy burden on the boarding-house keeper of deciding whether the lodger be certifiable or not.

\* \* The question of a lunatic treated in the circumstances mentioned in this query is covered by Section 315 (1) of the Lunacy Act, 1890. It reads as follows:

"Every person who, except under the provisions of this Act, receives or detains a lunatic, or alleged lunatic, in an institution for lunatics, or for payments takes charge of, receives to board or lodge, or detains a lunatic or alleged lunatic in an unlicensed house, shall be guilty of a misdemeanour, and in the latter case shall also be liable to a penalty not exceeding fifty pounds."

This section makes it clear that it would be illegal for a lunatic not under certificate to be received into furnished rooms, the relatives paying for the lunatic's board and lodging, and also for the services of a nurse. There is no distinction in principle between the boarding house and the nursing home. "Receiving to board or lodge" in the above section must be read as distinct from "taking charge." The opinion has been given by the law officers that if a lunatic is received to board or lodge in the house of one person, and another takes charge of him, both are subject to penalty. It is thus the person who takes charge of, who receives or detains, a lunatic contrary to the provisions of the Lunacy Act, who is liable to prosecution, rather than the practitioner who visits the patient. It is certainly difficult for a boarding-house keeper to decide as to the certifiability of a lodger, but in the event of a prosecution the court would no doubt need to be convinced that she could reasonably have been expected to know that the patient was insane. As it is quite possible that neither the relations, nurse, nor landlady would be aware of any breach of the law, a good deal of responsibility would seem to devolve upon the practitioner in attendance to advise as to the legality of the position.

### DANGEROUS EXHAUST GASES.

The engineering department of the Automobile Association points out that as the winter is coming on many owner-drivers will be carrying out carburettor and ignition adjustments in their motor-houses with closed doors. A word of warning, therefore, is directed against the danger of running an engine stationary for any length of time within closed premises. To form the gas required, petrol is mixed with approximately seventeen or eighteen times its weight of air, and, provided combustion is complete, the mixture is burnt to carbonic acid gas and water vapour. These ideal conditions, however, seldom obtain, with the result that the exhaust gases contain a certain amount of carbon monoxide. It frequently happens that a super-rich mixture is employed at closed throttle positions for purposes of easy starting or to obtain good "idling" of the engine. When running stationary, therefore, in the garage, carbon monoxide is likely to be present in the exhaust gases, and it is desirable to have proper ventilation either by keeping the doors open or by fixing an extension on to the end of the exhaust pipe carrying it through an aperture in the door or building.

### THE LONDON SCHOOL OF DERMATOLOGY.

In the paragraph describing the institution of a London School of Dermatology, published last week (p. 673), the name of Dr. James H. Stowers was inadvertently printed as Dr. J. H. Stiles. The error was unfortunate, because we understand that Dr. Stowers has been largely instrumental in carrying through the negotiations which led up to the present satisfactory position. In recognition of his services he was entertained to a complimentary dinner by his colleagues at the Trocadero last week, with Sir Malcolm Morris in the chair.

### MEDICAL GOLF.

THE autumn meeting of the Medical Golfing Society was held at Rye Golf Club on October 13th and 14th. The society wishes particularly to record its appreciation of the hospitality and great kindness shown it by the officials and members of Rye. Two fine scratch scores were recorded by Mr. Gillies (74) and Mr. Kolesar (76). The results of the competitions were as follows:

*Canny-Ryall Challenge Cup*.—H. P. Aubrey: 85-10=75. H. D. Gillies: 74+3=77. H. Wolseley Lewis: 85-7=78. T. P. Kolesar: 76+3=79.

*Scratch v. Bogey (under Handicap)*.—Sir K. Goadby: 2 down. H. Wolseley Lewis: 4 down.

*Foursomes v. Bogey (under Handicap)*.—H. A. Richards and W. Gilliat; W. L. Lamplough and H. D. Gillies.

The seventh bi-annual meeting of the Shropshire Medical Golf Association was held on the Wrekin course by the kind permission of the committee. The results were as follows:

*Medical Challenge Bowl*.—Mr. S. Bradford: 86-13=73. Dr. G. Lawrence: 84-8=76. Dr. W. H. Smith: 96-20=76. Twenty-six entries.

*Foursomes v. Bogey*.—Drs. J. Wheatley and T. R. Elliott, 4 down; Dr. Clarke and Mr. Edmund, 5 down.

Dr. G. Wedd of Wellington was unanimously elected captain and Dr. Elliott honorary secretary for the ensuing year. A very hearty vote of thanks was proposed to Dr. J. Wheatley, the retiring captain, which was received with acclamation. The next meeting was fixed for the end of May, 1924, on the Church Stretton links.

### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 38, 39, 42, and 43 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 40 and 41.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 187.

# REPORT OF THREE AUTOPSIES FOLLOWING CARBON TETRACHLORIDE TREATMENT.

J. F. DOCHERTY, B.A., M.B., TORONTO, DIRECTOR OF ANATOMICAL AND PASTEUR INSTITUTES, CANADA.

LUCIUS NICHOLS, B.A., M.D., CANADA, AND

DIRECTOR OF THE BACTERIOLOGICAL AND PASTEUR INSTITUTES, CANADA.

With the object of confirming the report that carbon tetrachloride may produce pathological lesions of the liver, a number of condemned prisoners were treated with small doses of the drug. Post-mortem examinations were made on three of the prisoners. In two cases the intestines were removed in three sections after double ligatures had been applied; the sections were opened and washed separately to determine the number of free and attached parasites in each.

Each prisoner received 4 c.c.m. of carbon tetrachloride, followed in two hours by 2 oz. of saturated Epsom salt solution. No food was allowed previous to treatment except in the case of No. 8825, who by mistake received his ordinary breakfast at 6 a.m., and was treated at 10 instead of 8 in order to permit the passage of the food into the intestines. One and a half hours after the administration of the salt they were allowed tiffin.

Prisoner 8825 received 4 c.c.m. carbon tetrachloride at 10 a.m., on February 21st, the salts at noon, and had tiffin at 1.30 p.m. The number of worms counted in the first twenty-four hours was: hookworms 101 (male 38, female 63), ascariis 1, excretory over 1,000. In the second and third periods of twenty-four hours no worms were found. The man was executed on February 21st. In the contents of the large intestine two oxyuris and two trichuris were found, and attached to its walls nine trichuris and twelve oxyuris. In the lower two-thirds of the small intestine three ascariis were found in the contents and one ascariis and one trichuris attached. Two ascariis were attached to the duodenum and upper third of the small intestine. Prisoner 8837 received 4 c.c.m. carbon tetrachloride at 8 a.m., the salts at 10 a.m., and had tiffin at 11.30. During the first twenty-four hours one hookworm (female) was found and one oxyuris. In the second and third periods of twenty-four hours no worms were found; he was executed on February 21st. In the contents of the large intestine eight hookworms (six male and two female) were found and two trichuris. Three other trichuris were attached to the walls. In the contents of the lower two-thirds of the small intestine one ascariis was found and two trichuris attached to the wall; no worms were found in the duodenum and upper third of the small intestine. Another prisoner 8832, received 4 c.c.m. of carbon tetrachloride, but in his case the worms were not counted, nor were the intestines examined. None of the patients made any complaint.

Sections of the organs were stained with osmic acid according to the method of Marchi. Sections also were stained by haematoxylin and eosin.

No. 8825.—The liver showed fatty degeneration, many of the cells containing fat globules; the largest of the globules measured about 10 microns. The kidney cells contained a few globules of fat. The spleen was greatly enlarged and showed pigment and atrophic changes due to numerous fatty degeneration, the kidney no recognizable changes.

No. 8832 showed no changes in liver or kidney.

**Conclusions.**  
1. A dose of 4 c.c.m. of carbon tetrachloride given as in the above cases may produce fatty degeneration of the liver.

2. Although numerous fat globules may appear in the liver cells apparently as a result of the administration of carbon tetrachloride, the changes in the liver are of a temporary nature and do not appear to contraindicate the use of the drug, because many patients have been treated with much larger doses and have not complained of any symptoms or signs of ill health arising in them. Further, many hundreds of school children have received doses of carbon tetrachloride, and in no cases has any sign of ill health occurred subsequent to treatment.

3. In case No. 8825 the changes in the liver were so marked that we would have expected signs of marked ill health during life, but these were absent; consequently it appears that much fat (presumably derived from fatty degeneration) may appear in the liver and yet be a matter of small importance as concerns the health of the patient.

and can be more or less influenced by nerve impulses from higher levels, especially by those which are concerned in emotional states.

Other centres, or pathways, are formed by education, "conditioned," and are therefore liable to various alterations and especially to inhibition.

Functional centres or pathways may be formed in abnormal states. Fixed ideas probably result from the establishment of certain pathways in the cortex of the cerebrum. In asthma afferent nerve impulses resulting from certain stimuli produce a reflex contraction of the bronchial muscle and a narrowing of the bronchioles. The reflex may become a "conditioned" one, and be induced by any afferent impulse resulting from a stimulus which has been associated with its occurrence. The pathways in time are so "grooved" that the reflex takes place very readily, and is excited by any afferent nerve impulse which has previously been associated with the asthma.

The phenomenon of pain, and especially of visceral pain, may be influenced in the same way. The frequent carriage of nerve impulses from the heart along the pain pathways results in a lessened resistance of the synapses along the pathways taken. The occurrence of pain is facilitated, and a condition of status anginosus may be set up in which afferent impulses from other sources may spread into the same paths and produce pain. An attack of angina may be induced in this condition by a carious tooth or other source of pain.

In the production of visceral pain the afferent impulses from the organ affected spread into the pain paths in the lower level of the central nervous system, but the sensation of pain is located in some part of the body wall which is supplied with afferent nerves the impulses in which are capable of exciting a more or less localized sensation. In the areas supplied by these various phenomena occur. Hyperesthesia is sometimes met with, and the margins of the hyperesthetic area are constantly varying in position. The hyperesthesia is probably due to a decreased resistance of the synapses leading to the pain pathways, so that nerve impulses which would not ordinarily cause pain now do so because they pass more readily into the pain pathways.

The fluctuation in the extent of the area affected may be due to variations in resistance of the synapses in the pathways of the afferent nerves coming from the borders of the area, and be ascribable to the phenomenon of fluctuations or variation in the actual units employed in carrying the nerve impulses.

But other changes than sensory are usually found. Increased tone, or the actual contraction of muscle, often occurs in the body wall. The rigidity of muscle, especially well seen in the abdominal wall as the result of irritation of an abdominal viscus, is a reflex phenomenon, and is subject to the same variations as that affecting the sensory changes. A temporary centre is created in the central nervous system, and afferent impulses from the irritated viscous make use of certain pathways with the production of a number of end-responses. If the afferent impulses are sufficiently numerous, or if there is any condition present which decreases the resistance of the synapses, the impulses may spread and occasion not only pain, hyperesthesia, and contraction of muscle in a definite area, but vomiting, cardiac, vasomotor, and other reflexes.

Sensation and reflex action are closely bound up together. Even visceral reflexes may be productive of sensation. Alterations in the heart beat, palpitation, respiratory disturbances, vaso-contraction, and vaso-dilatation give rise to subjective phenomena. Irritability, exhaustion, and depression are of common occurrence in ill health. The fatigue of a synapse renders that synapse more resistant to the passage of a nerve impulse, and fatigue of the afferent pathways should be a negation. But fatigue and the sensations met with in ill health are positive sensations and not mere negations. They are, as a rule, general and not localized to any particular part. Their cause is unknown, but must be sought for in some alteration in the afferent nerve impulses affecting the conscious state.

At any given time, the afferent nerve impulses from the various organs and pathways are forming in abnormal states and especially to inhibition.

## If you want a car—

**W**HY put by those savings until you have the price of it, when you might have the car NOW and be paying for it *as you save?* Or perhaps you have the capital laid by, but hesitate to break into it in order to pay cash.

There is no need. . . We supply ANY make of motor vehicle on the *lowest terms*, by a system of monthly payments. Dealing in thousands of cars of every make enables us to offer such big advantages.

*All transactions are conducted absolutely confidentially.  
Will you write for details naming the car you would like?*

THE TRADERS' GUARANTEE ASSOCIATION, LTD.,

## Heavy Price Reduction of Kalamazoo brings large rush of orders

Our drastic reduction in the price of Kalamazoo Loose-leaf Books has met with success even beyond our expectations.

Lawyers, Doctors, Hospitals, Asylums and Institutions of every kind are daily installing Kalamazoo, for Kalamazoo is for keeping both the primary and subsidiary

accounts and records of every trade and business, large or small.

The Kalamazoo has always been an economy, but at this new reduced price there is a bigger saving than ever in office costs.

If you have not yet sent your enquiry, fill in the coupon below and post to-day.

*The Manufacturers supply Kalamazoo direct to the users only—not through Stationers.*

BRITISH RIGHT THROUGH.

These cases of death are essentially those that one expects to be influenced by better feeding and general improvement of the conditions of living in the country with a low infantile mortality and of the occupation with a low infantile mortality. The lowest infantile mortality should throw some light upon essential causes of infant mortality. The lowest infantile mortality rates are found in the rural districts of the United Kingdom and on the west coast of Ireland. Perhaps the counties of Connaught for 1920 and Galway for 1921 may be mentioned as being the best illustrated by the rates in the province of Connaught. The death rates in the counties of Connaught for 1920 were: Galway 47, Mayo 49, Roscommon 48, Sligo 57.

But such a complete localization as we now know to exist was unsuspected, and it was largely on this account that so much interest was aroused by the excitation experiments of Ferrier.

But if excitation of a particular area of the cerebral cortex provokes certain movements, it does not follow that we are to regard that area as representing a nerve centre for governing or producing those movements unless removal of the area is followed by paralysis of the movements. We may leave out of present consideration whether the so-called centre is automatic—that is, works spontaneously—or whether it only represents the point of arrival of sensory impulses and the point of departure of the corresponding impulses to motor centres in the lower part of the central nervous system—that is, whether it is a reflex centre. For this question, which was warmly debated at one time, may now be considered to be definitely settled in favour of the second hypothesis. In either case the final result of excitation and of ablation will be in the first case production of definite movements, in the second the inability to perform them.

At the period I am speaking of, many of the facts had been established, but the explanation was a matter of controversy. There were, moreover, still certain parts of the hemisphere which Ferrier had not explored, or which in his hands had yielded negative replies. And the results of the extirpations which he had performed in conjunction with his colleague Gerald Yeo, then professor of physiology in King's College, were not altogether satisfactory, nor did they agree in certain particulars with the work of others, especially that of Herman Munk of Berlin, who was working on much the same lines both in the dog and monkey.

This, then, was a problem still needing elucidation, and when in 1883 I succeeded Burdon-Sanderson in the Chair of Physiology at University College it was one of the first investigations at which I resolved to work, especially with the view of determining more exactly the results of removal of definite areas of the cortex. Now Ferrier and Yeo's work—I am referring only to their earlier work, the later was accomplished under different conditions—had been done by pre-Listerian methods, and I felt convinced that this might be the source of some of the discrepancies exhibited, as compared with the results of Munk and others. My own surgical training was unfortunately also pre-Listerian owing to the slow progress which was made in London in the adoption of Lister's methods, and the active opposition with

which they were met by many of the leading London surgeons. I therefore recognized the necessity of securing as a collaborator a young and skilful surgeon thoroughly imbued with Listerian ideas and enthusiastically interested in physiology. You may easily understand that I had no difficulty in making my selection, for Victor Horsley fulfilled all these conditions, and we were already on terms of personal intimacy. Gleefully did he accept the proposition that we should carry out this work together, and many were the hours which we devoted to it. In every case the first part of an experiment consisted in exploring by induction currents, after the manner of Ferrier, the particular area we desired to investigate, and the second part in removing the explored area, re-covering the brain and sewing up the wound. In these operations we made use of every Listerian practice, including to our woeful discomfort the recently introduced carbolic spray—a source of endless objurgations!

To these operations Horsley brought a remarkable amount of surgical skill. Our quadrumanous patients were kept under the best possible conditions, and in most cases made speedy recoveries. It is not saying too much if I add that Horsley obtained from these experiments a surgical experience of a unique kind. This experience he was presently—in his capacity of surgeon to the great hospital in Queen Square—to apply to the alleviation of human suffering in a domain which even the boldest surgeons had not ventured seriously to attack.

There is no better illustration of the mutual benefit which results when Surgery and Physiology go hand in hand than the history of our early efforts in this field of investigation. The benefit to Horsley I have pointed out. And for myself, I acknowledge with gratitude the debt I owe to my colleague for the opportunity I was afforded of learning the application of Listerian surgery to animal experimentation, a

lesson the benefit of which I am more than ever conscious of after nearly forty years' experience, much as things have changed both in Physiology and in Surgery since that far-off, but never-to-be-forgotten time.

Our partnership was a fruitful one. We were able to extend Ferrier's observations in the monkey's brain to parts which he had not explored, although in this particular he had not left much for future investigation. But the young worker may take it from me who have grown old and experienced in scientific investigation, that if he wishes to discover new things he will do well to repeat with the aid of modern contrivances any experiment which has been long accepted as affording the last and most incontrovertible word on the subject. Almost certainly he will find some point which has been overlooked by the original investigator, and needless to say by those who have merely aimed at getting the same results. And almost certainly the exception will prove—that is, will test—the rule, and he may easily find that which has been looked upon from time immemorial as scientific gospel is badly in need of re-editing. In my experience nothing is so fertile in discovery as going carefully with one's eyes open, and with the aid of new methods, along a well worn track. I say with one's eyes open, for if one shuts them to everything that is not exactly what one expects to see many a discovery will be overlooked.

It is not my purpose to give an account of our work on the brain—work which, begun together, was eventually by force of circumstances carried on independently or in conjunction with other workers. One word, however, I would say about a trait in my colleague which, although in no way unfavourable to his character, rendered the actual conduct of our joint investigation somewhat laborious. He was too energetic. He would think nothing of performing several operations at a sitting, and acquired so much skill at them that they occupied a relatively small amount of time. But the operation was one thing, the study of the symptoms quite another. Now it takes a long time to make a thorough investigation of symptoms in the human subject—although in this case the subject himself can give much assistance. But when it comes to making the same kind of investigation in animals, and especially in monkeys, which are often wild, and the attention of which it is always difficult to fix, an unconscionable amount of time has to be devoted every day to each case. It so happened that just about this time Horsley was leading an extremely busy life. He was surgical registrar at University College Hospital—a position involving a huge amount of clerical work—and later assistant surgeon there; professor superintendent of the Brown Animal Sanatory Institution; assistant professor of pathology in University College; had a considerable if not very remunerative private practice; and, last but not least, was engaged to be married. The result of all this was that most of the observations on the operated animals had to be made by his colleague, and when there were several to be examined the amount of time that these occupied every day rendered the duty severe. All the clinical notes thus taken day by day had to be collated, and eventually boiled down—a process which involved many prolonged conjoint sessions. Upon the results of this collaboration I need not dwell. Are they not written in the chronicles of the Royal Society? And are they not decently buried in the *Philosophical Transactions*? May they rest there in peace!

The experience which Horsley had gained in these experiments—commenced in the laboratory at University College and continued at the Brown Institution—was invaluable to him in dealing with cranial surgery in man, when the position of surgeon to the Hospital for Nervous Diseases in Queen Square fell vacant Horsley received the appointment. He lost no time in applying the knowledge he had acquired in the laboratory to the operating theatre in the hospital. Paget gives an interesting and humorous account of the first operation he performed there for a cranial tumour (p. 120). It was upon a Scotchman, was in every way successful, and was witnessed by a distinguished company, which included Hughlings Jackson and Ferrier. It was, of course, followed by many others, and these were often attended by eminent foreign surgeons, for Horsley's reputation as a cranial surgeon soon became widespread.

those who operated by the lateral method as due to interference with the brain, but this could not be so, for exactly the same operation can be performed for exposure of the pituitary, but if it is left untouched no adverse symptoms follow. Moreover, one of my assistants, Mr. Norman Dott, himself a skilful surgeon, has recently devised a method of destroying the gland completely in the cat, by a process of electrolysis, without any exposure or any injury to the brain. The sella turcica is reached by passing a fine trochar conveying a carefully guarded needle along the outer margin of the orbit, and through the sphenoidal fissure. This needle conveys the necessary current and the whole operation occupies only a minute or two. By careful adjustment of the position of the electrolysis needle it is possible to destroy either the anterior or posterior portion of the pituitary. If the anterior part is destroyed, the animal will inevitably die within two or three days, a result precisely similar to that obtained by Paulesco, Harvey Cushing, and others, when operating on adult dogs by the lateral method.\*

Although Horsley had occasion to perform on the human subject a certain number of operations for removal of tumours of the pituitary, his physiological experience in connexion with this organ had not the same influence in determining the corresponding surgical proceedings in man as had the experiments upon the brain. This was partly owing to the fact that tumours of the pituitary are rare, and that the methods for getting at the pituitary in the human subject are different from those employed for animals. Moreover, such tumours are often very slow-growing, and are not attended with immediate risk of life; whereas complete removal of the gland is dangerous if not fatal. And with regard to tumours of the thyroid, they can often be successfully treated without operation, and only occasionally pass from the hands of the physician into those of the surgeon. But I have, I hope, said enough about the physiological and surgical work of Horsley to illustrate the subject of this address, the close relationship that should exist between Physiology and Surgery. Horsley himself laid particular stress upon this. Mr. Paget tells us that when in January, 1911, the first Lannelongue prize—which is to be awarded once in five years to the surgeon who in previous ten years shall have done most for the advancement of surgery—was presented to him:

"He spoke a few words of thanks . . . and said that his own country, which had long been under the influence of John Hunter, had later come under the influence of Claude Bernard, who had joined together physiology and surgery. That is what I have striven to realize. Unfortunately if surgical science advances with fair rapidity, its practice progresses slowly. That is because we are held in bondage by tradition from which we have difficulty in freeing ourselves."

Clearly he meant by this the supposed dependence of surgery on anatomy, when he himself so clearly saw that it is physiology which it must in future depend upon, or only so far on anatomy as mechanical considerations may render necessary.

#### WILLIAM SHARPEY.

I am now going to give you an illustration of the advantage of the association of Physiology and Surgery from the career of the most eminent surgeon of our generation, Joseph Lister. Lister was essentially and fundamentally a physiologist. He was easily the most distinguished pupil of William Sharpey, and William Sharpey was unrivalled as a teacher of physiology. This is the more strange, since Sharpey himself did little or no original work in the subject. Nevertheless, no one gave more encouragement to his pupils to conduct physiological inquiries or more sympathy in their researches than he. The failure on his own part to carry out physiological investigations was due to his training. This was wholly anatomical. When he went to study in Germany it was Rudolphi's dissecting room he frequented, not Johannes Müller's lecture room and laboratory. Had he attached himself to the last named, he would have consorted with all the great German physiological workers of the middle of the last century—Helmholtz, du Bois-Reymond, Ludwig, Brücke: or had he gone to Magendie in Paris instead of to the anatomical and

surgical schools there, he would have consorted with Claude Bernard, would have become the outstanding physiological investigator in Great Britain, and would have occupied the place in London which Bernard occupied in Paris. But the tendency of the Edinburgh School in his day was wholly in the direction of anatomy, doubtless owing to the fact that the anatomical chair in Edinburgh has always been occupied by a succession of pure anatomists; whereas, although there existed a chair of physiology even prior to that of anatomy (rightly known as the "Institutes of Medicine"); it was never held by a physiologist until the appointment of Rutherford in 1884, of whom I am myself the unworthy successor. Fortunately we have illustrious examples to the contrary now, but the anatomy of those days exercised an influence upon its devotees which was not favourable to active research and least of all to experimental work. It must further be remembered that Sharpey was actually a lecturer on pure anatomy in Edinburgh when he was invited to occupy the chair of general anatomy and physiology at University College. Up to that time he had not taught physiology, nor had he received any training in it, although he had interested himself in certain physiological problems, especially those connected with the growth of bone and the action of cilia. It was too late for him to undergo a fresh course of training, and he was busy with his new duties. He had, therefore, to get up his physiology as best he could. The Council of University College would have done well if it had given him a free year to study physiology in France or Germany, but in those days there seemed to be no idea that anything of the kind was necessary: the governing bodies of universities rarely do the right thing in these matters! So Sharpey had to be content to teach a subject in which he was only self-trained. The more credit to him that he became so successful. For it is certainly due to his teaching, both directly and through his pupils, that the physiology of the latter part of the nineteenth century became preponderatingly an English science. I trust we still remain in the forefront, but we must admit that other nationalities have during the last five and twenty years made notable advances and are able to challenge any predominance we may have had.

#### LISTER: PHYSIOLOGIST AND SURGEON.

If I have been led away by the reverence I have for his memory to speak at greater length of Sharpey than I had intended, I have justification for doing so because of his intimate connexion with Lister.

Lister, long before he was a surgeon, was an experimental physiologist, and he continued to be one throughout his whole career. He had had no opportunity of being trained in experimental work, but he was a born experimentalist and trained himself. Whether he would have done better to have worked with Claude Bernard in Paris or with Carl Ludwig in Leipzig must be a matter of opinion, but his self-training had at any rate the advantage of developing his originality. His first scientific investigations were made with the aid of the microscope—an instrument with which he had, through his father, the discoverer of the achromatic lens, been familiar from his earliest days. He was amongst the first to demonstrate the existence of a dilatator pupillae in the iris and to show that, like the sphincter pupillae, which was already known, the dilatator is composed of plain muscle cells. Many later observers, less skilful or less accurate than Lister, have denied the existence of this muscle, but his work has been vindicated and confirmed by the most modern methods of physiology and histology. He also published observations on the arrectores pilorum which confirmed those of Koelliker, and are especially remarkable because he used a new and now universally employed method—that of microscopic sections—for the investigation. Doubtless the student of the present day, familiar with paraffin-soaked tissues and mechanical microtomes, would despise the rough mode of preparation used by Lister, and thus described by him:

"A portion of shaved scalp being placed between two thin slips of deal, a piece of string is tied round them so as to exercise a slight degree of compression; the preparation is now laid aside for about twenty-four hours, when it is found to have dried to an almost horny condition. It then adheres firmly by

\* The details of this method will be published in the next number of the *Quarterly Journal of Experimental Physiology*.

tions are simple: more of the protective foods—fruits, milk, green vegetables, and fruit.

The water must be constantly on the move. The proprietors have their own well-boiling plant, and provide trucks lined with concrete bands, have a great variety of chaff cutters, and are fed by natural springs or artesian wells. The warmth of the well or spring water encourages growth at the bottom, and are fed by natural springs or artesian wells. The water must be constantly on the move. The proprietors have their own well-boiling plant, and provide trucks lined with concrete bands, have a great variety of chaff cutters, and are fed by natural springs or artesian wells.

[illegible]

of the living web of the frog's foot, would be undoubtedly a mistake: for no amount of verbal teaching could do for him what a glance through the microscope at that sight at once effects."

And after explaining at considerable length the relatively painless nature of physiological experiments as compared with the cruelties which are inflicted every day for the sake of improving the quality or appearance of food, or even in sports such as fishing, shooting, and fox-hunting, he points out that the sportsman is not commonly regarded as cruel because the inflicting of suffering on the hunted animal is not his main object (which is indeed merely the gratification of himself and his friends), and continues:

"But surely those who regard this amusement as justifiable are strangely inconsistent if they brand with the epithet cruel the man who performs an experiment upon an animal at great sacrifice to his own feelings and with every care to render the pain as slight as is compatible with the high object in view."

And in his evidence before the Royal Commission (on November 1st, 1875) he begins by stating that his first experiments upon animals had been made when he was altogether unknown as a person of any sort of reputation whatever: and "When I first took in hand to teach others I felt that there were some points on which I desired more information than I could get satisfactorily from any book, and my first experiments were performed with the object of preparing myself for teaching, while I was not a person of recognized scientific attainments."

With regard to his early experiments upon blood he remarked that they "had the effect of giving me a kind of pathological information, without which I believe I could not by any possibility have made my way in the subject of antiseptics; and that subject, I believe, is becoming recognized as one of considerable practical importance. I have often felt that without the basis which I derived from experiments on the lower animals, I should never have been able to thread my way through the very perplexing and apparently contradictory facts which I met with in the first instance." Also that throughout his whole career after that time he had found experimentation on living animals necessary, and that through the medium of that experimentation originally commenced with other aims he was gradually led "to the development of that method of treatment which is now known as the antiseptic system." Further, with regard to his work on catgut ligatures he definitely states that if he had not made experiments in the first instance on animals he would have had to perform them on man; there was no other alternative.

#### LISTER AND PASTEUR.

Great as was his work in surgery, Lister never ceased to be a physiologist; to the end of his days he was deeply interested in all forms of experimental work. He was scientific to the core. As we have seen, he insisted that experimental work was the basis of all his researches in antiseptics. His experiments in this as in other directions are characterized by meticulous accuracy, a character which is essential for all scientific investigations. First the facts were ascertained by observation and experiment; then marshalled and collated with observations made by others; the deductions checked by yet other experiments; nothing was left to mere supposition. In this way he arrived at his great generalization which at once transformed surgery from a mere art which might be practised by any ignorant person into a real science which could only be properly advanced by those who adopt the experimental method. Given an adequate knowledge of anatomy—a science which is essential to the physician as well as to the surgeon—the basis of training in both the branches of what is popularly known as the "healing art" must be physiology. Lister would never have arrived at the position he occupies in the history of surgery if he had not been first a physiologist. Doubtless he was fortunate in his opportunity. He came at the right time, just when Pasteur was engaged in the brilliant researches which indicated the essentially parasitic nature of disease. How eagerly Lister seized hold of that opportunity we read in his biography, and his own tribute to the aid he obtained from the researches of Pasteur is unstinted; nevertheless, he had begun his experiments be-

fore he had heard of Pasteur's. I do not know any surgical contemporary of his who could have taken advantage of the opportunity thus offered; at any rate it is certain none of them did so. They all had anatomy at their fingers' ends, but this was the only science which it was then expected they should know, and it did not lead their surgery far along the path of progress.

#### PHYSIOLOGY THE BASIS OF SURGERY.

It is an old tradition that Anatomy is the exclusive basis of Surgery, but I am happy to think it is every day becoming more of a tradition and less of a practice. Many modern surgeons both in this and in other countries are physiologists as well as surgeons: Physiology has given scientific support to their Surgery, and has been in turn materially assisted by it. It would be invidious for me to mention the names of living individuals, and in an assembly like this it is not necessary: they are known to most of you. Their researches are becoming every day more numerous. They admit that Surgery is based upon experiment, in other words, upon Physiology, and that there is no possibility of its advancing in any other way. Like every other science, surgery without experiment must stand still, and no surgeon has any right to experiment upon the human subject if the lower animals are available for the purpose. That those who are learning operative surgery are debarred by Act of Parliament from practising on animals, although permitted to make any experiments they think fit upon human patients, is an incredible piece of folly, and ours is the only country in the world in which so heinous a measure could have been passed into law; the only nation where misplaced sentiment is allowed to displace reasoning, and where the necessities of humanity are subordinated to those of the brute creation. I wonder, does the public fully understand that by the present law no student is permitted to perform any operation upon an animal with the object of enabling him to do the same operation upon man, and to acquire the necessary skill to do it without danger to his patients. Which of you, I may ask, would like to be a first patient to be operated on, even for so simple an operation as the extraction of the crystalline lens? Yet the skill of the operator *must* be acquired by experience, and therefore men, women, and children must take the place of dogs, cats, and rabbits! Truly we are a nation of Pecksniffs! As Sir Rickman Godlee pertinently remarks, the strangest anomaly, as it must appear to our less sanctimonious brethren in the rest of the civilized world, is that our law, while it forbids the granting of a special licence to a distinguished doctor to experiment on a chloroformed frog in his own study in pursuit of science, allows anyone who can afford it to hunt a stag to death, or set two greyhounds to course a hare, and wager money on the result.

While it is the case that the progress of surgery must depend upon physiology, it is equally true that the progress of physiology depends upon surgery. Without an adequate knowledge of surgery many experiments which are necessary for the advancement of physiology could not be attempted. I have already given you instances of this. But I will call to mind the experiments on depancreatized animals which are at present in progress—experiments which are filling not only the pages of the medical and physiological journals but even the columns of the daily press. It is not everybody who is endowed, as Lord Lister and Sir Victor Horsley were, with the requisite knowledge and skill in both subjects to work single-handed. At the present time team work, suitably directed, is all the vogue; and this is largely why our knowledge regarding insulin has made such rapid advances within so short a time. Surely such a combination of physicians, surgeons, physiologists, biochemists, pathologists has never before been assembled to conduct any investigation as those who have been working in Toronto. In every physiological investigation on animals one of the team at any rate should be a surgeon, and I can conceive of no more advantageous training for a young surgeon than that which he will obtain by taking part in such an investigation.

Examples of the mutual value of co-operation between

living room, were unnecessary and wasteful; and it is still a common practice whenever a case of either of these diseases is reported to "examine the drains," and when they are found pervious to the smoke test, as they so frequently are, to insist on a more or less costly reconstruction. From the point of view of the doctor also, when the source of infection of a case of diphtheria was obscure, it was hard to be deprived of the old fetish of drainage, always so convincing to the patient and his friends, provided they were tenants, but equally a matter of extreme skepticism on the part of the owner of the property.

To justify our attitude, once it was realized that the actual micro-organisms responsible for these diseases could hardly ever, if at all, be conveyed by air polluted by the drains, we had to fall back on the theory that the inhalation of such air "lowered the resistance" of the patient, and was thus indirectly responsible not only for diphtheria but for many other infections, especially of the throat. It is this theory which is now challenged, and inasmuch as the reconstruction of drains costs a great deal of money, it is, I think, our duty carefully to examine the theory, to ascertain how drain air lowers resistance—if it does—and, in fact, whether we are justified on these grounds in demanding a considerable expenditure by owners of property.

I must at this stage make it clear that I refer only to drains which are not gas-tight as proved by the smoke test. Drains which are so faulty as to permit pollution of the soil by liquid sewage, with all its putrescible organic matter and high bacterial content, are on an entirely different footing, and it would not, I think, be difficult to prove that such contamination of the soil might well be, and often is, a factor in the production of disease.

With regard to atmospheric pollution, however, recent hygienic doctrine is very subversive of once general opinions. "Sewer gas, once a hygienic bugaboo, is now not seriously regarded by sanitarians. People naturally cling to the idea that anything that smells bad must be detrimental to health; sanitarians know, however, that our sense of smell is a very poor sanitary guide. Sewer gas is nothing more or less than air containing the volatile products of organic decay coming from sewers and drains. Some of these gases are more or less poisonous, but not in the great dilution ordinarily found in sewer air. As a matter of fact the air of sewers is ordinarily free of dust and bacteria, higher in carbon dioxide—10 to 50 volumes per 10,000. It is absurd to regard sewer gas as the cause of diphtheria, typhoid fever, scarlet fever, and other communicable diseases."

I think the logical way of approaching the question is to consider first the antecedent probability of such air actually causing the alleged lowered resistance, or as it is often called in rather vague language, "lowered vitality of the tissues," and then to examine any available evidence as to its actual effect on human or other animals. The supposed effect must evidently depend on the presence of micro-organisms or of chemical substances of a more or less poisonous nature.

This has been the subject of so much research that it is only possible to refer briefly to a few of the results obtained. Taking first the chemistry of the subject, we may dismiss the slight excess of carbon dioxide as negligible from the physiological or pathological point of view. Sulphuretted hydrogen is, of course, a lethal gas when in sufficient concentration. It has been the cause of many fatal accidents to men working in connection with sewers, and was even described by Sir Benjamin Richardson as "the true disease-producing agent in sewer air."

"This gas is not, however, a normal constituent of sewer air, mainly on account of its great solubility in water, and it is only in exceptional circumstances, where sewage is stagnant and decomposing, that it is evolved in sufficient quantities to become poisonous. Drs. Haldane and Hurley found that the smell of sewer air was not due to H<sub>2</sub>S, but to traces of volatile aromatic bodies—indol, skatol, and the mercaptans. It must be admitted, I think, that the presence even in extreme dilution of such very unpleasant bodies in the air of a house might cause loss of appetite and even a more or less psychic nausea and sickness. But in my experience such odours are always the subject of early complaint and are remedied before any actual illness arises.

When we consider the bacteriology of the question we find again a mass of research work all of which tends to acquit sewer air of its supposed pathogenic properties. Most of the experiments carried out by such authorities as Milne in Paris, Haldane, Carnelly, and Delpeire in England, and Wilson and others in America, show that the bacterial count of sewer air is generally less than that of the outside air in the immediate neighbourhood, in spite of the enormous bacterial content of sewage. There is one important difference in this respect between sewer air and drain air, the latter being more liable to give a high bacterial count. This is because bacteria held in suspension in liquid sewage can only escape into the air as the result of splashing, which occurs much more frequently in drains than sewers. This effect of splashing, however, has been shown to be strictly localized and very temporary, the bacteria very soon returning to the liquid under the action of gravity. Both Delpeire and Wilson came to the conclusion that most of the bacteria in sewer air were derived not from the sewage but from the outside air.

Both chemical and bacteriologic results, therefore, indicate that the probability of air contaminated by sewers or drains causing disease, or even predisposing to it, is very low indeed.

We have next to consider what is known of the actual effects of the inhalation of such air on the living organism. Apart from experiment there is first of all the well known fact that men working continually in sewers are at least as healthy as any other section of the community, and that there is among them no excessive incidence of the diseases popularly associated with "sewer gas." That this is not shown merely by the fact that occasional workers in concentrated sewer air, such as the numerous experts who have carried out the researches I have quoted, have experienced no ill effects from their exposure to sewer air.

When we come to experimental investigation the results are very similar. In 1856 Dr. Alcock published the results of his experiments in "Putrid gases as predisposing causes of typhoid infection." He exposed rats, previously inoculated with attenuated strains of *B. typhosus* and *B. coli*, to the concentrated effluvia from an untrapped water-closet—a very different thing from sewer air or drain air—and found that under these conditions the susceptibility of the animals was enormously greater than that of the controls, 50 per cent. dying after inoculation, as compared with 5 per cent. of the controls. This experiment has, of course, no bearing on the effect of sewer air or drain air, as this is not what the animals were in fact breathing.

On the other hand, Professor Delpeire found no difference in the health of animals kept in a room in which the air was entirely derived from a Manchester sewer and in those kept in a room in which the air was drawn from an adjoining garden.

Wilson and Greenberg in America exposed guinea-pigs to strong odours and gases from decomposing faeces, and found a retardation of growth during the first week, after which the animals returned to the normal in health and rate of growth.

The last test which can be applied is the degree of association between the actual incidence of diseases of the type under discussion and defects in drainage arrangements. In Leeds a very careful investigation on these lines was made during the years 1899 to 1901. It was found that the percentages of drain defects in 5,512 houses where typhoid or diphtheria had occurred, and in 2,275 houses in which no disease had occurred, were respectively 27.94, 27.23, and 27.30—a virtual equality.

In Gloucester a similar inquiry showed that house-to-house inspection gave a percentage of 23.4 of drain defects, while in houses attacked by infectious diseases the percentage was only 11.5.

In St. Helens the house-to-house percentage was 21.4 with defects, in houses where typhoid had occurred 10.1, where diphtheria had occurred 10.1.

The evidence on the whole of this question is summarized in the admirable Report of the Departmental Committee on Intercepting Traps in House Drains, from which part of the material for this paper has been obtained. Dr.

months among native Indians and mixed bloods. During the entire period not a single case of cancer was brought to my attention, although everywhere I inquired, although every doctor was asked the question, and although I personally came in contact with more than two thousand natives. The diet is very simple and the habits of the people are very regular."

Dr. F. P. Fouché (BRITISH MEDICAL JOURNAL, June 30th, 1923) writes: "For six and a half years I was district surgeon in the Orange Free State. . . . During the whole of that period I never saw a single case of gastric or duodenal ulcer, colitis, appendicitis, or cancer in any form in a native, although these diseases were frequently seen amongst the white or European population."

Dr. Bernard Hollander, writing in the BRITISH MEDICAL JOURNAL, July 7th, 1923, says: "Thirty years ago I was interested in the causation of cancer when my friend, the late Sir Henry Morton Stanley, the African explorer, drew my attention to the fact he had observed, that the native races in the regions through which he had travelled were free from it. . . . only in coast towns, where natives mingled with Europeans, did cancer occur, and then only . . . one case in about ten or twelve years." Dr. Dyce Sharp (BRITISH MEDICAL JOURNAL, July 14th, 1923) fully confirms these statements as regards Northern Nigeria and Abyssinia.

I could furnish much more evidence showing that the freedom from any of the stasis sequence is due chiefly to diet, and to a lesser degree to the habits of these races. Place these people in a civilized community, as in the case of the American negro, and the diseases they suffer from are precisely those of the white man among whom they live and whose diet and habits they imitate.

#### DIET AND CANCER.

I think I have proved that the primitive races, while living in their normal conditions and surroundings, are free from certain diseases of the gastro-intestinal tract and from cancer, all of which exist widely in civilization and are apparently becoming more and more frequent. This is so obvious in the case of cancer that much attention has been drawn to this particular stage of the stasis sequence and an enormous amount of money and time has been spent in endeavouring to find the origin of cancer. The chief cause of the failure of these efforts is the fact that cancer is not recognized as a part of a mechanical sequence and as never affecting a healthy organ, but is regarded as a primary condition. The cancerous cell will only grow in a suitable soil, and that soil is provided by the prolonged action of toxins in the tissues.

#### CHRONIC INTESTINAL STASIS.

I will now proceed to the description of the condition I called chronic intestinal stasis, and will endeavour to show how it runs parallel with civilization, producing misery and disease in a progressive and disastrous manner.

Many years ago, while walking over a bridge in Paris with my old friend Moynihan, he said to me, "You have completed your work on the treatment of fractures: why do you not turn your attention to the abdomen?" That remark sank into my brain and I went up to Leeds and saw the magnificent work he was doing in the school on which Mayo-Robson had shed so much lustre.

On my return to London I applied to the gastro-intestinal tract the same mechanical principles that I had formulated from the study of the changes which ensue in the bodies of labourers which I had employed in the treatment of fractures. They are the following:

1. Pressure produces changes in the structure and form of the bones and in the form and function of existing joints, while it determines the formation of new joints.
2. Strain produces change in the form of bones, and in the form of existing joints and also produces new joints.
3. When, apart from the exercise of pressure or strain, it is important, from the altered mechanical relationship of the individual to his surroundings, that a mechanism should be modified or an entirely new one developed, such a change takes place.

#### Its Mechanical Effects.

These laws show that we have a definite mechanical relationship to our surroundings, and that any variation in that relationship is followed by corresponding changes in our mechanism. In other words, this is the basis of evolution. Realizing the fact that civilization, because of the variation from the diet and habits of primitive man, meant constipation or the delay in the passage of material through the gastro-intestinal tract, I argued with myself as to what changes would develop in the viscera and in their attachment in order to obviate as far as possible the ill effects which must otherwise ensue from the stagnation of the contents of this tract. In the case of the large intestine to oppose the elongation and distension of the bowel it would be advantageous to strengthen the layers of peritoneum which secure the gut to the abdominal wall.

It is the habit in civilization to regard a single formed motion a day as the normal, so that the individual is habitually constipated for at least twenty-four hours, and the products of the food consumed during that period are accumulated in the large intestine, and in the first instance in its termination. Therefore strain is experienced first upon the outer layer of the mesentery which fixes the iliac colon to the floor of the fossa, and this strain is greatest about the junction of the iliac and pelvic segments of the colon. Corresponding exactly to this strain there is developed upon the outer surface of the mesentery, extending from its base, streaks or bands of peritoneum, fibrous in appearance. These spread gradually along its outer aspect and as they grow they contract and shorten this portion of the mesentery, so limiting the range of movement of the portion of intestine which it secures. Later this new growth of tissue, or the crystallization of lines of force, extends to the outer wall of the large bowel and gradually encroaches on its circumference. Not only does it pin the intestine immovably in the fossa, but by its progressive attachment to the bowel wall it rotates it upon its long axis and reduces its lumen very materially, and consequently obstructs the passage of faecal matter through it. The contents of this portion of the intestine are usually firm and often hard in consistency, so that it is easy to realize how difficult it may be for the faecal mass to negotiate this obstruction, even when it exists only in a moderate degree. Any interference with the free functioning of this portion of the bowel is a serious obstacle to efficient drainage, and the more marked the obstruction the greater the delay of material in the entire gastro-intestinal tract proximal to it.

To this particular obstruction I gave the name of the "first and last kink"—the first because it is the earliest to form, and the last because it is the lowest in the gastro-intestinal tract.

I cannot exaggerate its importance, as I believe its capacity for harm is tremendous and far-reaching and that it is responsible for all the changes which are due directly and indirectly to chronic intestinal stasis. It spells the failure of civilization and is a veritable Pandora's box.

Consequent on the stagnation of material in the large bowel similar bands develop along the mesentery, securing the convexity of the loaded colon. These are most marked in certain situations, as at the splenic flexure, and again at the end of the ileum, where it is called the ileal kink. The secondary accumulation of material in the small intestine angulates the duodeno-jejunal junction, causing first dilatation of the duodenum and later ulceration of its first portion, spasm of the pylorus, dilatation of the stomach and its ulceration along the seat of strain—namely, the lesser curvature. This ulceration of the stomach tends readily to become cancerous.

The same tendency to the development of cancer occurs in the large bowel where angulated and obstructed, by acquired bands or by spasmodic action of the sphincter ani or of Mayo's circular band of muscle, in direct proportion to the degree of obstruction and to the increase in consistence of the faeces. The stagnation of the contents of the large

and presumed that no one would suggest that drain air had any connexion with the spread of scarlet fever or other infectious diseases.

Dr. JOHNSON SAUTY (Bournemouth) believed that many cases of chronic illness or debility were maintained by the inhalation of sewer gas, and that this was demonstrated by the improvement that followed removal to healthier conditions.

Dr. WYNN, in reply, especially thanked Dr. WYNTER Blyth for contributing to that Section the results of his original and most valuable recent research work. He thought those results largely confirmed his own conclusions. He had already emphasized the distinction between defects which only permitted the escape of air or other gases and gross defects which permitted the escape of liquid matter. The objection to privy middens did not depend only on their foul emanations, though these were much more serious than drain air and quite capable of producing loss of appetite and sickness. They were always breeding places for flies, and in one case he had been able to trace an outbreak of typhoid fever to the emptying of infected faeces from a privy midden on to an unpaved yard, whence the infected material was carried into the adjoining houses either as mud or dust. He honoured theory of bad drainage as a cause of unaccountable that to deprive the family doctor of the time-honoured theory of bad drainage as a cause of unaccountable that to deprive the family doctor of the time-

every effort should be made to trace disease to its true source. fession that they should continue to promulgate doctrines that they knew to be false, while it was essential that not think it was good either for the public or the profession that they should continue to promulgate doctrines that they knew to be false, while it was essential that every effort should be made to trace disease to its true source.

## CARBON MONOXIDE A PREDISPOSING CAUSE OF PULMONARY TUBERCULOSIS.

E. B. HAZLETON, M.D., M.C.R.

About twenty years ago I was consulted by a male patient, aged 38, who suffered from morning headache, anorexia, some shortness of breath on exertion, and lassitude. Remedies such as preparations of iron, arsenic, digitalis, failed to effect much improvement, and, some years after I first saw him, he contracted pulmonary tuberculosis. On visiting him for the first time in his bedroom I detected a distinct odour of coal gas. He had occupied the room for a period of ten years, and the conditions had been about the same during that time. I came to the conclusion that the first illness was due to the nightly inhalation of small quantities of coal gas.

From the observation of a large number of similar cases I was led to conclude that the inhalation of coal gas, even in very small quantities, continued for a considerable period, may be a predisposing cause of tuberculosis. Placed in order of quantity the constituents of coal gas are:

Hydrogen,  
Marsh gas (methane),  
Carbon monoxide,  
Olefin gas (ethylene),  
Acetylene,  
Nitrogen,  
Carbon and sulphur dioxide,  
Hydrogen and ammonium sulphide,  
Carbon disulphide.

Out of this list I only propose to consider the action of carbon monoxide.

A sample of air was taken from a bedroom in which there was a slight escape of gas. An empty oxygen cylinder, having the valve widely open, was left in the room overnight, and early in the morning a foot pump was placed on a level with a sleeper's head and the air of the room pumped into the cylinder to a pressure of 100 lb. per square inch, and the valve closed.

Mr. Wigginton, lecturer in the Department of Fuel Technology, Sheffield University, very kindly undertook the analysis of the contained air. As a result of the analysis we may conclude that where we are enabled to detect the

presence of coal gas in a room by the sense of smell, the amount of carbon monoxide present will be about 0.02 per cent., and that in quite a large number of cases 0.01 per cent. is present.

The blood of an average man is capable of absorbing 600 c.cm. of either oxygen or carbon monoxide, when it is said to be saturated. If both gases are present in the inhaled air the haemoglobin of the blood will combine with the carbon monoxide in preference to the oxygen—the ratio being 200 of the former to 1 of oxygen.

FIG. 1.—A type of gas bracket frequently fitted in bedrooms.

FIG. 2.—Showing a condition which nearly always results after some months' use. The retaining screw at the top of the tap becomes loosened and the tap sags downwards, permitting the gas to escape, as shown by the arrows.

FIG. 3.—Showing a simple remedy. By direct experiment it is found that the spring is unnecessary, as, if the tap be placed as shown, the force of gravity will be sufficient to keep the sides in close apposition and thus prevent all escape of gas.

The ordinary rate of breathing when a man is at rest is 7 litres of air per minute, of which 5 litres reach the blood, so that if the air of a room contains the very small quantity of 0.01 per cent. of carbon monoxide, then 0.5 c.cm. of this gas will reach the blood per minute; and assuming that all this is absorbed, in one hour the blood will absorb 30 c.cm. and become 5 per cent. saturated, and in eight hours will become 40 per cent. saturated.

Dr. Nere Foster and Haldane have, however, found in their investigations of mine air that only three-sevenths of the carbon monoxide which reaches the blood is actually fixed by the haemoglobin; hence in eight hours the amount of saturation would be rather over 17 per cent., and this amount of saturation is quite sufficient to produce the symptoms of morning headache, shortness of breath, anorexia, lassitude, and, after some months, anaemia. We can readily understand that, in consequence, there may be a distinct inhibition of phagocytosis and a lowering of the resisting power of the mucous membrane and epithelial lining of the bronchi to the invasion of tubercle bacilli.

Dr. WYNN (Sheffield) said the object of Dr. Hazleton's paper was very interesting in connexion with the previous discussion. There could be no question as to the harmfulness of coal gas even in very high dilution, especially in

F. GOWLAND HOPKINS, D.Sc., F.R.S.,  
PROFESSOR OF BIOCHEMISTRY IN THE UNIVERSITY OF CAMBRIDGE.

## LECTURE II.—RICKETS AS A DEFICIENCY DISEASE.

IN this lecture I propose to consider the evidence obtained in the course of recent experimental studies, which shows that a specific dietetic deficiency plays an important part in the causation of rickets. There seems no doubt that a vitamin is involved in this deficiency or I should not now be dealing with the matter. The evidence for this claim doubtless needs closer scrutiny than was necessary in the case of certain nutritional failures dealt with in the previous lecture. For this very reason, however, I have chosen rickets as the subject of my second discourse. It is well to avoid the danger of suggesting that in such studies experimental results are always easily obtained or interpreted, especially when the reproduction of a particular disease as defined by clinicians is in question. I do not think you will deny, however, that in its final outcome the experimental study of rickets has fully justified its pursuit. Another reason for my choice of subject to-day is the desire to pay a public tribute to the work of a friend whose successful efforts to throw light upon the etiology of rickets have, I feel, lacked proper appreciation in certain quarters.

The history of the recent experimental studies of rickets and of the conflict of opinion to which they have led is in itself interesting and instructive. Honest opinions held in good faith have sharply differed. Yet the ascertained facts are now grouping themselves in such a way that both sides in the conflict may come together with flags still flying. Each side has been right, but neither side (because of the tendency to take too narrow a view) has been quite right. I would like, perhaps, just to add that I think this qualification applies especially to the side which is not my own.

There have been many views concerning the origin of rickets, but of these three only need be in your minds. One has looked upon various defects in hygiene as responsible for the disease, but from these defects faulty diet has been, on this view, expressly excluded. A second view has attached, on the other hand, a special importance to diet. It is this view, of course, in its most modern form, which involves the conception of a specific food deficiency, that I am here to support. The third view has postulated infection as a factor in the causation.

In 1908 Dr. L. Findlay published the results of experiments upon dogs which, together with his experience as a clinician, led him to conclude, alike on experimental and clinical grounds, that confinement, with consequent lack of exercise, is the main factor in causing the disease. In 1919 appeared as one of the reports of the Medical Research Council the results of an important study carried out in Glasgow by Miss M. Ferguson. This work was inspired by Professor Noël Paton, and was published with an introduction by Dr. Findlay, who had himself carried out, several years previously, a similar investigation. Miss Ferguson's study involved a careful comparison of the economic conditions in rachitic and non-rachitic families respectively. It dealt with hundreds of families of which the food budgets and housing conditions were studied with great care. The general conclusion arrived at was that inadequate air and exercise were the most potent factors in inducing the occurrence of rickets. It was held proven that diet played no essential part in the etiology of the disease. Upon these experiments and observations, supported by some others made more recently, are based the views of what is sometimes called the Glasgow school.

In direct conflict with these views were the results of Edward Mellanby's experiments, of which a preliminary

account appeared about a year after Miss Ferguson's report, though they had then been long in progress. I feel it incumbent upon me to insist strongly upon the importance of the work of my friend and former pupil, because in certain quarters at least it was received with somewhat carping criticism, still not frankly withdrawn. Moreover, not all among the more recent experimentalists, whose work took origin from Mellanby's, and has in effect confirmed it, have given him sufficient credit as a pioneer. The earlier and chief part of Mellanby's work was done at Cambridge, with support from the Medical Research Council. Although I had no hand in it, I can testify to the care with which it was done and to the patient enterprise it involved. Mellanby was blamed at the outset for making public claims before his experimental results had been fully published; but I think we should all sympathize with the dilemma of young investigators to whom priority is important but who yet suffer from a praiseworthy desire to polish their work before publishing it. There was plenty of evidence behind Mellanby's first statements. The Medical Research Council was also blamed at this time because in the first edition of the monograph, for which the Council is responsible, dealing with accessory food factors, a claim, supposed to be premature, was advanced for the importance of a dietetic deficiency in the causation of rickets. I do not think, however, that there will be anything to withdraw on the appearance of the second edition of the monograph—which is imminent—though there are many facts, derived from various lines of study, to supplement what was said in the first edition.

Mellanby's main observations were made upon puppies, and one minor criticism of his method was that in comparative experiments he did not generally use individuals from the same litter. This may appear a small point, but it is one of some interest to which I should like to devote a moment. It is known in the case of several metabolic anomalies—alkaptonuria, for example—that they are inherited on Mendelian lines. I have recently seen at Cambridge an illustration of such inheritance in the case of an anomaly which was not apparent till the metabolism was experimentally studied. I will not be more precise in my reference as the observation is not mine and is not yet published. But suppose among dogs there exists a sharp variation in susceptibility to rickets (and this would seem to be the only justification for insisting upon the use of puppies from one litter), then if by chance either relative immunity from or hypersensitivity to rickets were a recessive Mendelian character, which from what I know seems by no means impossible, segregation might have occurred in the very litter chosen for experiment. This might entirely upset experimental comparisons. Two puppies from one litter may, of course, be more alike than any two not so related. They may, on the other hand, in respect of a particular character, show exceptionally sharp contrasts. For studies in metabolism I would choose, whenever possible, dogs of the same breed and age, but I would rather select from an average population than from the same litter. This, however, is a digression.

Mellanby, as I have said, has worked on a large scale, and must by now have employed in experiments nearly 500 dogs. His general plan of work was on the following lines. Having established a standard diet which could be relied upon to produce rickets in puppies—an end that could be attained without much difficulty—he replaced one constituent of this diet by other material and observed the effect in respect of the development of rickets. In particular he exchanged one form of fat for another, and found that, while one fat might have little or no preventive power, another might prove strongly prophylactic. He found, further, that the fats most potent in this respect were those which on other evidence were known to contain the highest proportion of vitamin A. As I can testify, Mellanby arrived at this result without bias of any kind. It was originally unexpected by himself. I ought to mention that for the diagnosis of rickets he employed, apart from the general appearance of the animal, x-ray photography, histological examination, and also estimations of calcium in the bones.

Mellanby found that cod-liver oil was particularly potent in the prevention and cure of the experimental rickets. If

that deficiency in an organic dietary factor closely associated with (but not necessarily identical with) the vitamin A plays an important part in the causation of rickets.

The further evidence which I would now like you especially to consider comes from the study not of animals but of children. Before dealing with this truly conclusive evidence I must, however, make brief reference to the remarkable studies which have demonstrated that radiant energy directly influences the processes of calcification in the body.

It is remarkable how long information with regard to the effect of light upon rickets has been in the literature without receiving general notice. As far back as 1890 Palm called attention to the fact that sunlight is very potent in preventing or curing the disease. Later, in 1912, Raczyński showed that sunlight has a remarkable effect in promoting mineralization of the tissues generally. In 1919 Hulschinsky showed that precisely the same result can be got by the use of the radiations from a mercury-vapour quartz lamp, and demonstrated the actual healing of rachitic lesions in children under the influence of these radiations. Hess of New York has with his co-workers confirmed and extended these observations. They have, moreover, been extended to experiments on animals. McCollum and his colleagues have shown that in the case of rats the antirachitic effect of light is similar to that of cod-liver oil in correcting dietetic deficiencies. If, for instance, the diet lacks vitamin "X" exposure to sunlight, or to the mercury lamp radiations, will prevent the occurrence of rickets. On the other hand, as Hess, and later, Goldblatt and Soames, have shown, if the diet is satisfactory, and contains a sufficiency of the vitamin, rickets never develops, even when the animals are kept in the dark. It would seem, indeed, as though certain radiations and the influence of vitamin may each act vicariously for the other in regulating the mineral metabolism of the body. This is a truly remarkable relation. When we understand it we shall possibly know much more than we know now about the functions of vitamins. Now since a proper supply of sunlight is certainly a factor in hygiene, and a vitamin is no less a factor in diet, I think I was right in suggesting earlier in this lecture that the facts as now known should form a basis for an honourable peace between the two opposing schools of thought then mentioned.

In extending, however, the study of radiation from rickets to the more fundamental phenomenon of growth itself, Miss Margaret Hume has discovered facts which show that light may, after all, not act vicariously for the vitamin nor (as has been suggested) bring about a photosynthesis of that factor in the body. Rather does it render more mobile the residual stores of the vitamin already in the tissues. When the vitamin is absent from the food exposure to suitable radiations will maintain growth for a period, but not, it should be noted, indefinitely. Miss Hume concludes from her work that (in relation with growth at least) light can neither create nor be substituted for the vitamin; it appears to act as an economizer or activator of the stores so that a deficiency in the supply is less readily felt. When, however, the stores are exhausted the animal fails.

The briefest reference only can be made to another and most fascinating aspect of this subject. In quite another connexion it had been shown by Kestner that exposure to air previously irradiated may have the same effect upon an animal as direct exposure to the radiation itself. Acting upon a hint from Professor Hans Meyer, Miss Hume determined to test whether this would prove to be the case in connexion with her own studies. She found that as a matter of fact rats fed upon a diet deficient in vitamin A, when kept in glass jars containing air which had been exposed to the mercury-vapour quartz lamp for ten minutes every second day, showed definite prolongation of normal growth when compared with control animals not so treated. Miss Hume's work was mainly done in Vienna as part of the enterprise to which I would now direct your special attention.

Most of you will doubtless realize that I allude to the studies carried out in Professor Pirquet's clinic by Drs. Chick, Dalyell, and Mackey, Miss Henderson Smith and Miss Hume. These five women workers went to Vienna under the combined auspices of the Medical Research Council and the Lister Institute. They submitted themselves to three years' exile in order that studies might be made where material was abundant and conditions ideal. The conditions were indeed ideal, and all who read the Medical Research Council's report which deals with the enterprise will admit that the final results were proportionally clear and unequivocal. The intention underlying the enterprise was to study the effect upon the prevention and cure of rickets in children of diets poor or rich respectively in those fats which contain vitamins. The organization of Pirquet's clinic was such as to convert this comparison into an experiment perfectly controlled. It was an experiment wholly justified because the control diet, relatively deficient in the vitamin, was one which all the infants would have received but for the arrival of the British workers. It was a diet, too, of which the details had been carefully worked out by Professor Pirquet himself, than whom there is no higher authority on such matters. Before the observations under review were made he fully believed in its efficiency, the belief being based in the main upon its adequacy in respect of calories. The experiment gained greatly in accuracy because advantage was taken of the remarkable organization for the quantitative feeding of children which Professor Pirquet has established, and because all factors of faulty hygiene could be completely eliminated. The accommodation available permitted observations to be made upon sixty infants at any one time. The methods used for diagnosis must, I think, satisfy the most critical. Fortunately the work of the latest year was done with full knowledge of what had been discovered elsewhere concerning the influence of sunlight and irradiation. This factor was therefore controlled and separately studied. I cannot, unhappily, stop to put the details of the results before you. It seems enough to quote from the statement with which Professor Pirquet has prefaced the Medical Research Council's report.

"When Dr. Chick and her colleagues on behalf of the Medical Research Council and the Lister Institute began their work in my Klinik in 1919," he writes, "I had little expectation that it would lead to results of much practical value. At that time I was of the opinion that a vitamin deficiency in our ordinary diet was a very exceptional occurrence, as, for example, in case of infantile scurvy (Möller-Barlow disease). With regard to the etiology of rickets I held the view that it was an infectious disease, widely prevalent in this part of Europe, producing severe symptoms only in case of those children who possessed special susceptibility as the result of an inherited tendency, of a faulty diet, or of defective general hygiene. I imagined rickets to be a disease comparable to some extent with tuberculosis."

Professor Pirquet was indeed a critic not easily convinced, but later in his preface he states:

"The crucial experiment was thus successfully made. The British workers succeeded with the accuracy of a laboratory experiment, in a city where rickets is extremely prevalent, in maintaining a large number of artificially-fed babies free from the disease, and further, in the same wards, were invariably successful in healing children admitted with rickets already developed."

"With this the chain of evidence appears to me to be complete that animal experiments upon rickets are applicable to man, that rickets is a disease of nutrition, and that deficiency of fat-soluble vitamins in diet is an essential cause of the disease."

Thus is Edward Mellanby's pioneer work confirmed and his conclusions justified.

## Treatment of Glaucoma.

Mr. H. TAYLOR read a paper on the operative treatment of glaucoma. He first showed several cases of successful trephining for chronic glaucoma. In one case, there was a hieb in the left eye, but no rise of tension. In his opinion iridectomy was only successful when a piece of iris was prolapsed in the wound (iris inclusion) which might act as a drain. He divided chronic glaucoma into two classes: (1) when a small amount of drainage only was necessary to re-establish equilibrium; and (2) where a considerable iris inclusion might be all that was required, in the second class sufficient drainage could only be procured by trephining. The bleb over the trephining hole was undoubtably objectionable, but it was doubtful if it could be avoided. If the case trephined was in the first class no case could be placed. Iridectomy, even if the iris was included, might not function in the first class and more certainly would not in the second class. Therefore, from all points of view he considered that sclero-conal trephining should always be practised. Further, he was firmly of opinion that if chronic glaucoma was once diagnosed no time should be wasted on palliative treatment, but an operation should be performed as soon as possible. Lieut.-Colonel HERBERT, Dr. BARRY, and Dr. DAVIS took part in the subsequent discussion.

Dr. GALT showed microscopical slides of *Aspergillus niger*, ringworm in hairs, normal pancreas, pancreas from an advanced case of diabetes in an adult and also in a child aged 9. Mr. A. J. HITCHCOCK gave details with reference to the slide of *Aspergillus niger*.

## SURGERY OF THE LARGE BOWEL.

The annual meeting of the London Association of the Medical Women's Federation was held on October 5th at the Elizabeth Garrett Anderson Hospital, when Dr. LOUISA MANTON, the retiring president, vacated the chair to her successor, Miss M. CHADBURN.

Miss Chadburn first discussed briefly some of the points raised by Sir Humphry Rolleston in his recent address at the London School of Medicine for Women, and then proceeded to give an address on the surgery of the large bowel. She surveyed the diseases of the large bowel which had fallen to her care during the years 1865-22, excluding pressures effects on the bowel from outside, cases of hæmorrhoids, fissures, fistulae, and complete perineal tears. It had been found difficult to trace cases, but it was encouraging to find a few cases of carcinoma of the rectum, sigmoid, colon, and caecum living as long as eight to fourteen years after radical excision. In regard to the malignancy of diseases was noteworthy, of the operable when first seen, and the advanced stage of those that were operable, and the rarity of the discovery of malignant disease of the large bowel at an early stage, were striking points. Of 181 consecutive cases 121 were carcinomata, of which 62 were operable when first seen. Miss Chadburn did not believe that any more radical operation than the abdomino-perineal excision would be discovered for rectal carcinoma. She considered that it was now possible to say that operations on the large bowel were as radical as was physically possible. Advance must be sought either in obtaining cases earlier for treatment, in some treatment other than operative, or in prevention. Earlier diagnosis seemed the most hopeful means of improving results, but unfortunately the onset was insidious. Miss Chadburn concluded that operations for carcinoma in the large bowel were borne well, especially in early cases.

## Reviews.

## PSYCHOLOGICAL TYPES.

Professor C. G. JUNG has written an important work entitled *Psychological Types*, or the *Psychology of Individuation*, which he describes as the fruit of nearly twenty years' work in the domain of practical psychology. Psychiatrists who gained inspiration from his earlier work on dementia praecox may perhaps regret that the author did not confine his attention to those clinical studies which promised so much, but the trend of his investigations into delusional states, and his own natural bent, have led him, perhaps inevitably, to apply his empirically gained knowledge to the problems of life as a whole. Some readers may feel that his outlook is philosophical rather than scientific, but whether this be so or not, his knowledge of human nature has not been evolved from the depths of an armchair, after the manner of some philosophers, but is based upon an intimate knowledge of the inner mental life of all sorts and conditions of men. This experience of human nature, together with a wide knowledge of human aspirations as expressed in ancient and modern literature, have enabled him to produce a highly original work which will be read with advantage by those who interest themselves in the problems of life and personality.

Though we are all aware of the fact of individuality, we should find it difficult to define the differences between one individual and another. The academic psychologist has left the matter severely alone, and it is to the dramatic novelist, or biographer to whom we turn for convincing studies of abnormal persons have been presented by medical psychologists; but the most comprehensive attempt at a psychological classification of personality types is undoubtedly that evolved by Jung in the book before us. He has found that humanity can be divided into two contrasting types, which he terms *introverted* and *extraverted* respectively. The destinies of the extravert are conditioned more by external objects, and the introvert more by his inner self—by his subject. The interest flows outward in the one case, inward in the other. To quote from the author: "If a man so thinks, feels and acts, in a word so lives, as to correspond directly with objective conditions and their cause, whether in a good sense or ill, he is extraverted," but in the interest, "the subject is and remains the centre of even introverted types, or the *Psychology of Individuation*, by C. G. Jung, translated by H. G. Weir, London, 1921, (Demy 8vo, pp. xiii+232).

impulses from the higher levels. The incoming nerve impulse may cause inhibition of expiration and excitation of inspiration or the reverse. In the case of some afferent impulses their action may be directed solely to the production of inspiration or expiration. The application of cold to the skin brings about inspiration, while stimulation of the mucous membrane of the larynx excites a violent expiration with the other movements associated with coughing.

The passage of the nerve impulses through the centre may be varied in a number of ways. They may be directed into the efferent inspiratory and expiratory neurones alternately for different periods of time. If alternating rapidly the movements of respiration are quick. If alternating slowly the respirations are slow. The depth of the respirations probably depends upon the number of neurones concerned as well as upon the rhythm. It is possible that we have constant variations going on in the neurones affected during quiet respiration, first one set and then another coming into action, fluctuation taking place just as it has been shown to occur in the capillary circulation. When the stimulus to respiration is powerful the impulses spread very widely over the efferent neurones, but alternate between inspiration and expiration. The number of neurones concerned in respiration is very variable. Even in quiet respiration the neurones affected are spread over a wide area, but in dyspnoea practically all parts of the lower level of the central nervous system are concerned on the efferent side. The nerve impulses seem, however, to come from the centre in the medulla oblongata and to be distributed from it to the efferent neurones.

If automatism is claimed for the centre it is difficult to see where this property is to be located. It cannot be in the efferent neurones, for the centre of the phrenic nerve shows no sign of it when isolated. If in the afferent nucleus of the vagus nerve, it is difficult to see how respiration is made to alternate between inspiration and expiration and is at the same time subject to control by other incoming nerve impulses. It is much simpler to regard the neurones as having the same property as other neurones elsewhere, and as responding only to nerve impulses coming to them from other neurones. The centre is affected in disease. Its activity is increased in febrile conditions, and Haldane has shown that fatigue of the centre results in rapid shallow breathing. It is unlikely that fatigue or the toxins of disease act primarily upon the cell bodies of the neurones; they are far more likely to bring about their results by action upon the synapses on the nerve pathways in the centre. In the rapid shallow breathing of fatigue the blood may be imperfectly aerated, yet the stimulus of the hydrogen ion content is ineffective and does not bring about a sufficient depth of respiratory movement to ventilate the lungs. The special receptor, if it exists, might be the site of the fatigue, but fatigue of the centre may be caused by breathing against a resistance, and in such case there is nothing to fatigue the special receptors. The evidence seems clearly to be in favour of a synapse fatigue.

More is probably known about the respiratory centre than about any of the others, but our knowledge of it is far from satisfactory. The vasomotor centre is another of the vital centres which presents similar problems. Unlike the respiratory centre it is unaffected by voluntary influence but is subject to changes by the nerve impulses underlying emotional states. It is also supposed to be directly influenced by conditions of the blood. Here again such influence is better explained by changes in resistance of the synapses than by the postulation of special receptors in the centre.

Drugs are often stated to exert their influence by direct action upon certain centres. Apomorphine is said to stimulate the vomiting centre. If it does have a direct action upon the centre the site of its action is most probably upon the synapses and not upon the neurones or special receptors.

If we are to regard the neurone as a conducting mechanism and not as an automatic generator of nerve impulses, the nerve centre may be looked upon as a net-

work of nerve pathways which are so arranged as to conduct the nerve impulses in definite channels for the sake of obtaining a co-ordinated end-result. Certain pathways are, as it were, canalized in the centre, and incoming nerve impulses are directed and distributed to the efferent neurones. The controlling influence in the nerve centre is not the nerve cell but the synapses. We prefer to define the nerve centre as a collection of nerve pathways or neurones which are so arranged that nerve impulses coming into them are co-ordinated and distributed to bring about a definite end-result. The co-ordination and distribution effected in the centre depend upon changes in the synapses. The synapse is the all-important factor in the centre, and is the probable site of the action of fatigue and of other extraneous influences.

#### FORMATION OF PATHWAYS OR CENTRES.

Some pathways or centres are preformed in the embryo. Their anatomical arrangement is such that afferent impulses coming into them bring about a definite end-result which is not the product of education. The vital reflexes of the body are examples. Most of these, such as the respiratory, cardiac, and vasomotor reflexes, remain during the whole of life. The sucking reflex of the newly born child is an example of one in which the centre is preformed but does not persist. Other centres are educated, and we have seen that the process of education consists largely in the cultivation of the synapses so that nerve impulses pass readily over some and not over others.

An interesting and important development of the postural reflexes takes place after birth in the child, and the pathways of the nerve impulses concerned are slowly educated. The attitude of the child, or its postural position *in utero*, is one of flexion. In the newly born child the muscles which produce flexion at a joint are more developed than are the opposing muscles. After birth an erect posture, or one of extension, is gradually assumed, and a long time elapses before the extensor muscles attain the relatively greater strength which characterizes them in the adult. With the development of new reflex paths the extensor muscles gradually assume a predominance. Failure to develop the new postural reflexes is a matter of considerable clinical importance, and, according to Blundell Bankart, is the real cause of the deformities which so commonly appear in the lower extremities and spine. Talipes, lateral curvature, and other deformities are explainable by the failure of the nervous system to lay down the particular pathways or centres which are requisite for the proper development of the muscles.

The response of the plantar reflex in the child differs from that in later life, and the explanation is probably to be found in the difference in development of the nerve pathways for the flexor and extensor muscles at the ankle-joint.

In the case of all reflexes which are in constant action there must be some provision against fatigue. This is probably effected by there being a sufficient number of pathways in the centre to allow of fluctuation. We may assume that the units in action are constantly changing within certain limits. When all are called into action simultaneously greater effects are produced and fatigue is more readily caused. An increase in the number of pathways concerned in a reflex may lead to greater spread in the central nervous system, but it is probable that some other factor is necessary such as the increased frequency of the impulses carried. The increased frequency may be the main factor in overcoming the resistance of other synapses and so causing spread beyond the usual channels. We know that the impulses do spread widely under certain conditions, and the spreading may be the result of a massive action of afferent impulses, or of a lessened resistance of the synapses as is induced by the action of strychnine.

Reflex pathways or centres which are preformed and persistent are concerned in the production of the unconditioned reflex. Such reflexes take place with a considerable degree of certainty although they are not altogether independent,

rectum; his object is to obviate the effect of gravity in the loop passing up to the splenic angle, and so to get rid of the symptoms rather than deal with the prosis.

The various forms of suspension operations, so popular of late, he condemns as unsound in principle. The mesenteries, he holds, are not suspensory ligaments, and it is no use hitching them up and expecting the stitches to withstand the movements of the bowel and support the continual drag of the loaded colon, where the intra-abdominal pressure is reduced. The discussion of intestinal stasis and chronic constipation occupies a good deal of space; of the latter, two types, obstructive and atonic, are recognized. Contributory factors are diet, sedentary habits, the mechanical disadvantage of the colon in the erect attitude, and weakness of the mechanical wall. As to the pathology of stasis, the views of the mechanical school, headed by Sir Arthur Keith, and of the operative camp, under Professor Adams, are fully discussed; the conclusions reached are that the mechanical move is in itself no longer tenable, and that the condition is more probably due to some neuro-muscular inco-ordination of the colon wall—the view supported by Sir Arthur Keith.

All the surgical lesions of the colon and rectum are taken up in turn, and dealt with in separate chapters. They are discussed with due attention to detail, cases are quoted to illustrate special points, and each section bears the mark of practical experience. The literature about diverticulitis, for instance, which has grown so rapidly in recent years, has been thoroughly sifted. In the treatment of this condition the author advises colostomy followed by excision later, after there has been plenty of time for the inflammation to subside. In the course of the discussion of malignant disease of the rectum and colon some encouraging results are recorded. For the years 1915-1921 the author's operative mortality for perineal excision of the rectum in 109 cases was a shade over 8 per cent.; of 56 patients operated on in 1915-1917, 17 were alive and well five years after the operation (47 per cent.). The abdomino-perineal operation, although theoretically ideal, has a high operative mortality, varying from 25 per cent. to 40 per cent. It is a pity that reliable statistics as regards recurrence after this operation have not been included in the text to round off the comparison between the two operations.

Many of the finer points of operative technique are discussed, especially the various methods of colon anastomosis, and their relation to the blood supply. This book should enjoy a wide popularity among all interested in the practice of surgery, for its contents are as valuable to the practitioner in the country as they are to the surgeon in a city.

#### GASTRO-ENTEROPOSOIS.

Dr. Corey almost apologizes for publishing his monograph on *Gastro-enteroposis*. Most of his friends advised him against appearing in print, but a chance meeting with Sir Berkeley Moynihan and the encouragement received from him made Dr. Corey change his mind, and the book has appeared with an appreciative note by Sir Berkeley, who is described by the author as "maintaining an attitude of benevolent and dignified tolerance." The author's purpose has been to assemble all the important facts on this subject and to co-ordinate them into a clinical syndrome in the hope that it may form a basis for future investigation. The book should therefore command the attention and respect of all surgeons interested in abdominal surgery, whatever their own views may be, for the problem attacked is trivial of debatable matter, has given rise to highly conflicting opinions, and has been the cause of much harmful surgery. The author quotes and discusses the work of many surgeons, not only that of American, but that of Sir Arthur Lane, Walton, Waugh, and Wilkie in this country, and of the Scandinavian surgeon Rossing.

Detailed descriptions of the relations of the abdominal viscera are given and discussed from many points of view. *Gastro-enteroposis*. By Robert C. Corey, M.D., F.A.C.S. Surgeon Monographs. ## DISCUSSION ON

FACTORS CONTRIBUTING TO THE RECENT  
DECREASE IN INFANTILE MORTALITY:*Are such Factors likely to be Permanent or Temporary?*

## OPENING PAPER

BY

JAMES WHEATLEY, M.D.,

County Medical Officer of Health, Shropshire.

In introducing this discussion I must apologize for the incompleteness of my paper, but I hope this will be remedied by subsequent contributions to the discussion. The subject is a large and complicated one and worthy of very careful research. It seems to me that the best plan is to set down the indisputable facts that appear to be relevant and afterwards to state various deductions and opinions. These facts may be well known to most of you, but nevertheless it is necessary to state them.

For most of my facts I am indebted to the excellent reports of the Registrar-General, for which Dr. Stevenson is presumably still responsible, although his name no longer appears in the reports. I am also greatly indebted to the medical officers of health of the large towns and counties, who have very kindly supplied me with facts and opinions relating to the decrease of mortality in their areas, and to Dr. A. D. Symons, one of my assistant medical officers.

The statistics here given relate not only to the fall in the infantile mortality in the country as a whole and in relation to areas, quarters of the year, and causes of death, but also to the smallness of this mortality under certain conditions. These latter figures throw considerable light upon the probable causes of the fall.

TABLE I.—England and Wales: Birth Rates, Death Rates, and Infant Mortality Rates.

| Years.    | Birth Rate. | Death Rate. | Infant Mortality. | Increase or Decrease. |                                                                                                    |
|-----------|-------------|-------------|-------------------|-----------------------|----------------------------------------------------------------------------------------------------|
| 1841-1850 | 32.6        | 21.6        | 153               |                       |                                                                                                    |
| 1851-1860 | 34.1        | 21.2        | 154 ...           | + 0.6                 |                                                                                                    |
| 1861-1870 | 35.2        | 21.3        | 151 ...           | 0.0                   | Education Act, 1870.                                                                               |
| 1871-1880 | 35.4        | 21.3        | 149 ...           | - 3.2                 | Public Health Act, 1875.                                                                           |
| 1881-1885 | 33.5        | 18.7        | 130 ...           | - 6.7                 |                                                                                                    |
| 1886-1890 | 31.4        | 18.5        | 145 ...           | + 4.1                 |                                                                                                    |
| 1891-1895 | 30.5        | 18.5        | 151 ...           | + 3.9                 | Housing of the Working Classes Act, 1890.                                                          |
| 1896-1900 | 29.3        | 17.6        | 156 ...           | + 3.2                 |                                                                                                    |
| 1901-1905 | 28.2        | 16.0        | 138 ...           | -11.5                 | Midwives Act, 1902.                                                                                |
| 1906-1910 | 25.3        | 14.4        | 117 ...           | -15.2                 | Education Act, 1907; Notification of Births Act, 1907; Children Act, 1903.                         |
| 1911-1915 | 23.6        | 13.8        | 110 ...           | - 5.9                 | National Insurance Act and Tuberculosis Order, 1911; Notification of Births (Extension) Act, 1915. |
| 1916-1920 | 22.1        | 13.7        | 90 ...            | -18.1                 | V.D. Regulations, 1916; Maternity and Child Welfare Act, 1918.                                     |
| 1921 ...  | 22.4        | 12.1        | 83                | -11.0                 |                                                                                                    |
| 1922 ...  | 20.6        | 12.9        | 77                |                       |                                                                                                    |

It is apparent that there was no fall whatever in the infantile mortality between the years 1841 and 1860, and that since then the fall has been large and continuous. The fall in the birth rate commenced twenty years before the

fall in the infant death rate and during this period it fell 17 per cent.

The fall in the general death rate had been almost continuous, although comparatively small in amount (19 per cent.), for the sixty years previous to the fall in infantile mortality. If the period of 1840 to 1920 be divided into two periods of forty years, the first period shows a reduction of the general death rate of 6 per cent. and the second of 30 per cent. The second period practically begins with the passing of the 1875 Act. We have, then, a fall both in birth rate and death rate up to 1900 without any fall in the infant death rate. We must either accept that the fall in the birth rate and the conditions causing the fall in the death rate—presumably improved sanitary conditions—had no effect on infantile mortality, or that whatever effect they might have had was neutralized by some other adverse circumstances. As I shall point out later on, I think adverse circumstances did exist and were a condition of increased material prosperity without a corresponding improvement in education and conduct—a condition, in my opinion, particularly adverse to infant life.

The next important point arising out of this table is that the fall commenced long before the passing of the Notification of Births Act, the Maternity and Child Welfare Act, the Education (Administrative Provisions) Act, the Children Act, and the Midwives Act, and before any considerable direct efforts to reduce infant mortality. The fall did not commence until twenty-five years after the Public Health Act, 1875, with its sanitary service, so that this Act alone appears to have had little influence. The Education Act, 1870, would hardly be likely to produce any considerable influence upon infant mortality for about a generation, or, say, thirty years, taking into consideration the gradual development of the work and the fact that it could only become operative as the school children became parents. This would bring us to 1900. As many of the facts to be set out seem to show that the decrease of infantile mortality is due to a general raising of the intelligence of parents, it is of interest to see that the commencement of the decline of mortality corresponds fairly well in point of time with the improvement of the general education of the people.

The following table has been compiled from the replies received from the medical officers of health of the towns and counties.

TABLE II.—Fall in Infant Mortality in Certain Towns and Counties grouped according to Date of Commencement of Infant Welfare Work.

| Group and Date when Health Visiting Commenced. | Decrease in Five-year Periods stated as a Percentage of Period immediately preceding. |               |               |               |               |               |
|------------------------------------------------|---------------------------------------------------------------------------------------|---------------|---------------|---------------|---------------|---------------|
|                                                | 1896 to 1900.                                                                         | 1901 to 1905. | 1906 to 1910. | 1911 to 1915. | 1916 to 1920. | 1921 to 1922. |
| I. Between 1800 and 1905 (13 towns)            | +4.4                                                                                  | -13.9         | -14.2         | -6.8          | -16.9         | -12.5         |
| II. Between 1906 and 1910 (9 towns)            | 0.0                                                                                   | -13.3         | -16.0         | -6.3          | -13.6         | -12.7         |
| III. Between 1912 and 1913 (6 towns)           | -1.8                                                                                  | -15.0         | -19.0         | -6.1          | -12.9         | -17.0         |
| IV. Between 1914 and 1916 (22 counties)        |                                                                                       | -12.7         | -10.3         | -9.5          | -15.8         | -11.25        |
| V. Between 1917 and 1920 (10 counties)         |                                                                                       | -15.2         | -17.9         | -8.9          | -14.1         | -12.7         |

In Groups I and II the health visiting was not complete for considerable periods averaging 7 to 14 years.  
In Group III the health visiting was complete in periods averaging from 3 to 7 years.

In Group IV the health visiting was complete in 2 to 3 years afterwards.  
In Group V the health visiting was complete in 2 years afterwards.

The grouping of these towns and counties is probably not by any means satisfactory, as the commencement of health visiting may mean very different things in different localities. The health visiting may rapidly develop into a satisfactory scheme or it may drag on as a very ineffective service for many years. Still, broadly speaking, the groups of towns and counties do represent those that commenced child welfare work early and those that commenced at later periods.

Examination of the table does not show any influence of this early or late commencement of child welfare activities, nor does it reveal any material difference in the

## British Medical Journal.

### THE INSURANCE CRISIS.

IN THE SUPPLEMENT this week we publish a full account of the Panel Conference, containing a verbatim report of the statement which the Chairman of the Insurance Acts Committee made to the representatives. This statement was ordered to be sent to every insurance practitioner, and when it is read it should make the main issues clear and provide a view of the situation which may well be put to members of Parliament and others who are interested. This is very necessary, for many of the articles and statements in the lay press during the last fortnight—even some attributed to doctors themselves—appear to indicate a considerable degree of inaccuracy and confusion of thought.

As Dr. Brackenbury showed in his forcible and lucid address, there are at the least three important points that it seems necessary to emphasize. The first of these is that the present action by the profession is being taken not against what is sometimes spoken of as the "panel system," "as such," but in order to avert the danger of a debasement of that system. The provision of medical attendance and treatment by means of a national health insurance system has been declared by both the Conference of Local Medical and Panel Committees and the Representative Body of the British Medical Association to deserve the united support of the profession for its continuance and improvement. No important body of practitioners, however, would consent to become or remain members of a service the terms and conditions of which militated against good professional work being done or tended to bring about a less satisfactory standard of attendance among the industrial population than among those of other classes. Almost continuously since 1913, in spite of the very adverse influences of war and unemployment, practical experience has led to a steady improvement of medical benefit under the system which began to operate in that year. Further important improvements have been suggested or agreed to by the Panel Committees and the Insurance Acts Committee, to become operative at the beginning of next year. The effect of these improvements would be nullified by any such drastic reduction of remuneration as that proposed by the Minister of Health under the pressure of the Approved Societies. It would be nullified, too, by any such additional obligations as those societies are still urging the Ministry to impose upon insurance practitioners, restricting their liberty to undertake legitimate private work, allowing complaints to be made against them by society agents even contrary to the wishes of the patients themselves, and making requirements with regard to medical certificates such as are unheard of in any other comparable sphere. Neither the buckstering spirit nor the low ideals of the societies are tolerable to a profession which has wider notions as to what a national health service ought to be and a greater regard for the well-being of the wage-earners as patients. The medical profession will continue to fight strenuously for the maintenance of a health insurance service worthy alike of the nation and of itself.

In the next place the present action of the profession is not against the Friendly Societies as such in their own sphere, but against their usurpation of a place in the system which is not properly, and was never intended to be, theirs. As dispensers of cash payments in incapacitating sickness or disablement, of maternity benefit, and of some additional benefits, they serve a very useful purpose, and their work may be of great value to the community. There are ways in which they can be of much help both to patients and to doctors. Their diversity is not necessarily a drawback, but the large numbers of societies and branches, the complexity of their administration, the complicated organization of some of them, and the very small membership of others, are certainly disadvantages. It is probable that the establishment of suitably constituted committees, comparable to Medical Service Subcommittees, to which complaints as to their administration of sickness and other benefits might be referred for investigation and public comment, would result in the restriction of irregularities and negligences; and it is certain that their power of veto over the use of national funds and their extending administration of such additional benefits as are obviously "not legally" of the nature of medical benefit, ought to cease if either the national Treasury or the medical profession is to maintain independence. But the Friendly Societies in their own place and the profession in its own place are an integral part of the insurance service, and there is no fundamental reason why they should not co-operate for the national good.

The third point to make clear is that the protest of the profession against a drastic reduction of the insurance capitation fee is not a demand for any further contribution from the taxpayer. The claim is that the remuneration of insurance practitioners, as ascertained on its merits, should be a first charge on the National Health Insurance Fund, and that this Fund is, and is likely to continue to be, in a position to bear it. This claim as to the substantial stability of the aggregate, is established by the report of experts after full investigation; it has not been controverted by the Ministry; and it is allowed by some of the most astute officials of the Approved Societies themselves. Payments out of the Fund are, according to the statutory provision, supplemented to the extent of two-thirds from Government grants; but the same proportionate supplement out of the taxpayer's pocket has to be made whatever be the purpose to which the payments are directed. Any reduction of the capitation fee, therefore, does not advantage the taxpayer at all.

These three negative points should be borne in mind. The medical profession no doubt realizes them, but it seems needful to impress them on the public and on Parliament. The more clearly they are understood the more valuable will be the increasing support already being given to the profession by the press and public opinion. But the profession must rise, and we believe has already risen, to the heights of its own opportunity. It has an active and efficient organization and experienced and able leaders, who have not hesitated to give a strong lead. Never were its members so united in their aims and their determination. The Minister of Health has left only one way open for professional action. It behaves every insurance practitioner who has not already sent his resignation from the service to do so without fail and at once. Such a demonstration of professional feeling and professional power will be in itself

recent years a parent could neglect or be cruel to his child to any extent if he only avoided death, with the resultant coroner's inquest.

This increased responsibility has no doubt been brought about by various causes. The Education Act of 1870 must have been the initial cause, but it has been increased very largely in recent years by a variety of social work, particularly under the child welfare schemes, the medical inspection of school children, and the Children Act. The war has probably also been a powerful educative factor.

The decrease of alcoholic intemperance which undoubtedly has taken place in recent years has probably contributed considerably to the fall in infantile mortality. This decrease, however, must be considered as one of the conditions brought about by general education. The greatly decreased number of convictions for drunkenness and the diminished consumption of alcohol may be taken as proofs of a decrease of this form of intemperance, and its effect upon infantile mortality is shown in one direction by the decrease in deaths from overlaying (from 2.05 in 1891-1900 to 0.60 in 1920-21).

It seems extremely probable that the major part of the fall in infantile mortality prior to 1911 was due to a general raising of intelligence and responsibility. Before 1911 special measures directed towards infant welfare could have had no appreciable influence, and for reasons given elsewhere the fall cannot be attributed largely to improvement of general sanitation, improved material conditions, or lessened birth rate. To what extent the fall since 1911 has been due to general education and to what extent to special education, it is difficult to say. It is something like the problem of the soil and the seed in the causation of infectious disease; without the preparation by general education the special teaching later on would probably have borne little fruit.

The low mortalities in the professional classes must, I think, be attributed to education and a higher standard of conduct rather than to material advantages, although the latter no doubt have contributed to the result.

#### SPECIAL EDUCATION IN EVERYTHING APPERTAINING TO HEALTH.

Under this heading is included, first and by far the most important, the influence and teaching under the maternity and child welfare schemes, but it also includes the educational influence of medical inspection of school children, the tuberculosis scheme, the establishment of district nurses and trained midwives, and other educational influences.

Most of us must, I think, have come to the conclusion from a close knowledge of the facts that a considerable proportion of the fall in the last four or five years at least has been due to the various activities under the maternity and child welfare schemes, but it is most difficult to prove this by statistics. The decrease of 11.5 per cent. in 1901-5 and of 15.2 per cent. in 1906-10 must have been due principally to general conditions antecedent to child welfare, although even in these years the pioneer work of some of the towns may have had a general educational influence throughout the whole country in altering our ideas of the value of infant life.

The decrease in the period 1911-15 was slower, being only 5.9 per cent. It included, however, the very abnormal year of 1911 and the first seventeen months of the war. This period was followed by a decrease of 18.1 per cent. in the next five years and a further decrease of 11 per cent. for the two years 1921 and 1922. This very large fall of about 30 per cent. in seven years, following upon a fall of about 40 per cent. in the previous fifteen years, seems to point to some special cause operating during the later period. It was the period of greatest child welfare activity. Previous to it the schemes were limited to considerable centres of population and even in large towns they were very incompletely developed. The war was a large disturbing element, with its greatly decreased birth rate, increase of female employment, shortage of milk, and probably increase of natural feeding in consequence. Those who attribute the low infant mortality in the last three years of the war to low birth rates are faced with a rise of 25 per cent. in the birth rate and a fall of 15 per cent. in the

infant mortality in 1920, 1921, and 1922, although it may be argued that the bad effects of a high birth rate are only felt after its continuance for a considerable period.

It must, however, be admitted that there are facts which are against the assumption that infant welfare work is the chief determining factor in the decrease. These facts have been discussed in connexion with Tables II and III. The great decrease of mortality in rural districts (almost equal to that of the towns), notwithstanding that the child welfare schemes are by no means so complete and comprehensive and were brought into operation much later, may be partly due to the educational work of district nursing, which has undergone great development. It is probable, too, that with an equal amount of education greater effects can be produced in rural districts, owing to the better opportunities of carrying out directions regarding fresh air and sunlight. The same reason may perhaps explain the much greater decrease in the South and Midlands compared with the North of England (Table III), although the North, having had a much higher initial rate, presented a greater scope for reduction. Probably the amount of time spent out in the open air rather than in a hot stagnant nook in the kitchen is a most important factor in influencing not only the general health of the infant but also in reducing a disease like summer diarrhoea, which is perhaps too much regarded solely from the point of view of food infection.

The fact that the decrease of infant mortality since 1911 has been mostly confined to the third quarter of the year, while that prior to 1911 was fairly evenly distributed throughout the year, appears to indicate new causes for the later period. I think the nature of the fall, particularly the fall in infantile diarrhoea, fits in very well with the supposition that the new causes at work are the child welfare activities.

#### Fall in Birth Rate.

This has been discussed and reasons have been given for thinking that it is only a minor contributing factor.

#### Improved Standard of Living.

The evidence goes, I think, to show that improvement in wages without improvement in education and standards of conduct, results on the whole in more drunkenness, a greater carelessness, lessened natural feeding of infants, and a consequent increase in infantile mortality. Certainly the low mortality of 1921 and 1922 corresponded with much unemployment and low wages, judged by purchasing power.

Dr. Findlay, in his report on the causes of infant mortality to the Medical Research Committee, says:

"The unlikelihood of the wage element being a factor of any moment is supported by the fact that in times of famine and industrial trouble the infantile death rate usually falls. For example, during the year 1912 the number of people involved in disputes causing stoppage of work and the aggregate duration of working days lost was the highest on record, and yet, with the exception of 1916, the infantile mortality was the lowest ever recorded in most of the chief towns of Scotland and England."

The Registrar-General, in his report for the year 1911, says:

"The mortality of miners' infants is disproportionately high, especially in view of the fairly high wages earned by these men. They are certainly much better paid, and consequently in a better position to provide for the welfare of their infants, than the unskilled and casual labourers of the towns who form the bulk of Class 5, while their wives are as a rule not compelled to assist in earning the family living, yet at each of the five age periods the mortality of their infants is higher than that of Class 5 with the single exception of the second, 1-3 months, where it is only a trifle lower."

Miners had the highest infantile mortality for the year 1911, of eight classes into which the Registrar-General divides the occupations. Miners, we know, are exceptional people, their housing is exceptional, and their wages have on the whole been higher than those of the working classes generally. The conditions under which they live vary greatly in different parts of the country, but speaking generally there is not a dense aggregation of houses on area. I think this must be accepted as an instance of wages being ahead of education and ideals.

Wages, estimated by their purchasing power, underwent a very marked and almost continuous increase from 1849

The second inoculation was without any evidence of scarlet fever, some throat accompanied by a rise of temperature without any rash, and one developed sore throat but had no fever or rash. The other four of this series were inoculated with an undiluted suspension of the haemolytic streptococcus on the thirteenth day after inoculation with the filtered culture; forty-eight hours later scarlet fever developed. A consideration of this evidence makes it likely that the two cases of experimental scarlet fever reported were caused by the haemolytic streptococcus isolated from the patient.

Thus, evidence is steadily accumulating from different parts of the world in favour of the view that a certain type of haemolytic streptococcus may be responsible for scarlet fever, but we cannot yet determine whether by quoting the praise-worthy caution contained in the sentence with which the last article referred to concludes: "These experiments do not establish the conclusion that all cases of scarlet fever are caused by the haemolytic streptococcus described."

INTESTINAL STASIS AND CANCER.

body of material essential to life, and incidentally are liable to bacterial invasion and the absorption of poisons; that disease elsewhere in the body may have an intestinal origin is of course beyond dispute. As antecedents of cancer, this sequence of events must be included among the diseases thus induced in the alimentary canal—for example, the influence exerted by intestinal infection and toxæmia on the body generally is a large problem and deserves serious consideration. It is almost too obvious to remark that health and growth largely depend on the absorption of normal food products from the alimentary tract, and that therefore a pathological change in the gastro-intestinal functions cannot fail to be reflected in disorder of the habit of growth and functions of the body. On page 745 Sir Arbuthnot Lane reiterates his belief in the harmful influence of constipation, which he ascribes to the diet of civilization, and proceeds to the conclusion that cancer is the last stage in the sequence of its evil effects. Thus degenerative and cystic changes in the mamma, regarded as due to toxins absorbed from the intestines, are commonly associated with and may precede carcinoma of the breast.

While the exact cause of malignant disease is not yet revealed there is much evidence, both clinical and experimental, that chronic irritation induced by various agents such as soot, tar, arsenic, parasites (*Bilharzia*, *Sphenaria neoplasma*), x-rays, and perhaps may be followed by carcinoma. These irritants act locally in a somewhat intensive manner, and considerable time elapses before carcinoma develops in situ; it might, therefore, be thought to strain an analogy to argue that poisons absorbed from the gastro-intestinal tract, which would necessarily be much diluted, can so modify the habit of cellular growth that malignant disease would result. There is as yet no convincing proof of this sequence, and it must be further admitted that clinical evidence so far as it goes does not condemn Sir Arbuthnot Lane's contention that the cancerous patient is always the subject of chronic intestinal stasis. Indeed, it would be pressing the argument rather too far to suggest that intestinal stasis is a necessary antecedent to all forms of malignant growth—for example, those in early life. But because there are obvious difficulties in the way of accepting such a proposition it would be equally unwise to neglect it.

potential bearings? For this and for reasons of health there can be no doubt that Sir Arbuthnot Lane's emphasis on the prevention of chronic constipation by ordinary dietetic care and if necessary by paffin, massage, and a suitable belt, is eminently sound. When prevention has failed and operative interference becomes necessary he now advocates a much less drastic procedure than in the past, and has found that by thoroughly treating the junction of the iliac and pelvic colon, where "the last link" occurs, a cure is effected, and thus the considerable risks and drawbacks of colectomy are obviated.

A special congregation of the University of Manchester will be held on November 10th, when the Earl of Crawford, K.T., will be installed as chancellor and honorary degrees will be conferred on a number of distinguished persons, including Dr. J. G. Adams, F.R.S., vice-chancellor of the University of Liverpool, Sir Arthur Keith, F.R.S., conservator of the museum of the Royal College of Surgeons of England, and Sir J. G. Frazer, F.R.S., author of *The Golden Bough*.

The external surface of the body is mainly a defensive covering, whereas the linings of the alimentary and respiratory tracts provide for the entrance into the

Sir Arbuthnot Lane was generally recognized at present—namely, that its disposing influence is by no means confined to the oral and lingual surfaces. Sir Arbuthnot Lane has for years insisted on the importance of intestinal stasis in the causation of a large number of morbid conditions; his far-reaching thesis has aroused much criticism, and it is perhaps not untrue that a superficial familiarity with his views, and especially the heroic remedy of colectomy, have led to some want of respect. It may, however, be noted that Dr. T. G. Adamson, who in 1914 (*BRITISH MEDICAL JOURNAL*, 1914, 177) submitted the conception of intestinal stasis and toxæmia to considered criticism, contributed somewhat repellant chapter to Sir Arbuthnot Lane's symposium on *The Operative Treatment of Intestinal Stasis* (Oxford Medical Publications, fourth edition) in 1918. Indeed, it may well be that in future years Sir Arbuthnot Lane will be recognized as a prophet of the next many years crying in the wilderness before.

## SUMMARY OF CONCLUSIONS.

My conclusions are that the fall of the infant mortality rate has been due chiefly to education. The earlier part of the fall was probably principally due to the operation of the Education Act of 1870, raising the intelligence of the people and gradually increasing the sense of responsibility of parents. The latter part of the fall was probably brought about by improvement of general education and by the special educational influence of the child welfare schemes, aided by the educational work of the tuberculosis and medical inspection schemes, the establishment of district nurses, etc., and other similar work.

How much of the later fall should be attributed to special and how much to general education it is impossible to say. There are probably many minor contributory factors—such as diminishing birth rate, cleaner milk, better medical, nursing, and midwifery services, diminished horse traffic, tarred roads, and improvement of sanitation.

In attributing such a large influence to education I do not wish to belittle such important matters as pollution of air with smoke, overcrowding, and bad housing; but I believe that these are only very specially potent when combined with ignorance and carelessness, and it is the combination of these conditions that has caused the very high rates of our industrial towns of the North. Every sanitary worker knows that the evil effects of a house grossly insanitary in construction and situation may be enormously reduced by scrupulous attention to all the details of good house management.

It is in education and creation of a sense of responsibility, and not in the material conditions, that so much improvement has taken place. Everything, I think, points to the improvement being permanent and progressive. The decrease since 1901, taken in five-year periods, has been large and uninterrupted. It has affected every type of district and every part of the country. Not only so, but the fall has been equally continuous in all the big groups of disease except those due to conditions before birth. If any considerable proportion of the fall could be attributed to climatic conditions, such as mild winters, or to periodicity of infectious disease, we might have real setbacks, but I consider the evidence is strongly against this. We shall, no doubt, have slight setbacks owing to conditions favourable to diarrhoea, and possibly to severe outbreaks of measles, whooping-cough, and influenza; but apart from these, in my opinion, the improvement will be progressive as long as education keeps ahead of material advancement. A sudden and very marked increase of prosperity without time for a corresponding advance in education and conduct is the only condition that would, in my opinion, produce any considerable increase in our infant mortality. This, however, is extremely improbable.

## DISCUSSION.

Dr. HERBERT PECK (M.O.H. Chesterfield R.D.C.) said that while he agreed with Dr. Wheatley on most points he thought the latter had underestimated the effect on infant mortality of the general improvement in sanitary conditions, especially the progressive elimination of privy middens and their conversion to the water-carriage system. He also believed the introduction of summer time had a beneficial effect on the general death rate, and especially the infant mortality rate, since it secured an additional hour of daylight if not of actual sunlight during a considerable portion of the year.

Dr. H. B. BRACKENBURY (London) considered that since it was known that a low infantile mortality might be found in selected localities or among selected classes in which the conditions varied in many respects, it was desirable to secure a record of the variations in infant mortality in such special classes or groups of circumstances. Such an investigation might throw valuable light on the question as to which factors were of the most practical importance in reducing the death rate. It seemed to be established that a dirty atmosphere had a considerable effect in increasing infantile mortality, but it was also evident that education was very powerful as an influence in this sphere. The general education begun in 1870 produced its effects, as

would be expected, about thirty years later, and the effects had been continuous. Special education in personal and domestic hygiene had begun between 1901 and 1910 and we should see whether this produced a similar effect in the years immediately to come. The educational work of child welfare centres should, on the other hand, produce an immediate rather than a remote effect, and it was doubtful whether such an effect could be shown statistically. The beneficial effect of these centres—especially if conducted as educational and not as treatment centres—combined with home visiting on the comfort and well-being of many homes and children could not be doubted, but was nevertheless permissible to be sceptical as to the permanent effect on infant mortality.

Dr. D. C. KIRKHOPE (M.O.H. Tottenham) agreed the education had had a powerful influence on the decrease of infant mortality, especially the education of mothers in their homes by the health visitor. In the poorest locality in Tottenham the introduction of a voluntary child welfare scheme had been followed by an immediate and marked reduction in the heavy infant mortality, and as the work extended the fall in the rate increased. The instruction given at the centres was also of great importance and the attendance there of mothers with their babies tended to create a friendly rivalry in connexion with the progress of the children which could not fail to have a marked effect.

Dr. CLARK TROTTER (M.O.H. Islington) contended that the value of the education given in the course of home visitation had been underestimated by some of the previous speakers. Unless the welfare centre were most intimately associated with home visiting it did not reach the right cases. Good wages did not necessarily imply the most judicious expenditure of the money. In one town the infant mortality had been almost halved during a year of severe trade depression. The children of those out of work and their mothers had been fed by voluntary agencies and the staff of health visitors increased. He did not agree that the decrease in mortality could be mainly due to the Education Act of 1870. The real education of the adult, he considered, was acquired after his school life. The publicity given to health matters in the press and the vast improvement in the conditions of the working classes generally were, in his opinion, the most important factors. A man out of work now was looked after in many ways and his children did not suffer as they did prior to 1870.

Dr. H. SCURFIELD (late M.O.H. Sheffield) found himself largely in agreement with Dr. Wheatley, but was inclined to attribute more importance to the factor of a safer milk supply in the form of dried milk. He quoted the late Dr. Ewart as having shown that a probable factor in the increased infant mortality in the last decade of the nineteenth century was increased contamination of the milk supply owing to the removal of the consumer further and further from the producer, and that the improvement in the mortality rate coincided with the extended use of dried milk. It had to be remembered that the use of dried milk affected not only the purity of the milk as distributed but limited the probabilities of pollution in homes with unsatisfactory means of storage. In making a comparison with the conditions in Connaught, Dr. Wheatley had omitted to mention freedom from venereal disease and the abuse of alcohol by mothers, both of which factors were stressed in the Irish Carnegie report. Again, one had to remember that the ideals of family life in Ireland had not been destroyed by the industrial revolution and the agricultural revolution which occurred in England in the reign of George III. It was probable that in such circumstances a religion which held up high ideals of motherhood had never lost its effect. The teaching of domestic hygiene in schools was generally regarded as important, but unfortunately it was expensive owing to the need for providing special centres. It was accordingly the first thing to go when the cry for economy in educational matters became insistent. With regard to the future he anticipated a reduction in neo-natal mortality when the new midwifery was established.

Surgeons' Hall, and the picture now in the possession of the Royal College of Physicians appears to be a replica. It was to the acumen of Dr. Innes Smith, who is a collector of medical portraits, that the discovery of the replica was due; he saw it in a dealer's shop, recognized the subject, and acquired it. It is an important addition to the fine gallery in the possession of the College.

PHLEBOTOMY IN THE MONASTERIES.

At the meeting of the Section of the History of Medicine of the Royal Society of Medicine held on October 17th, Dom Louis Gougan, O.S.B., made an interesting communication on phlebotomy in the monasteries. In mediaeval times blood-letting was very common throughout the monastic houses, and nuns as well as monks were periodically bled. The frequency of this practice may have been due to the sedentary and unhealthy mode of life in the cells and cloisters, and to the need for an effective prophylactic against the temptations of the flesh. In some religious houses it was done monthly, except when a feast intervened; in others the monks were bled every six or seven weeks; in others three, four, or five times a year, according to the rule of the Order. In particular the Canons Regular had fixed days for phlebotomy. Often the procedure was laid down with much precision with regard to place and time of day, the prayers and ritual to be observed, the person who should perform the operation, and even the costume to be worn by the patient. Bandages of special material were occasionally prescribed, and directions given for a preliminary warming of the arm. Detailed instructions governed the patient's diet and regimen during the period of rest after phlebotomy, and his relief from the full rigour of monastic discipline. The mediaeval chroniclers examined by Dom Louis Gougan indicate that this relaxation from discipline after blood-letting often succeeded in loosening the patient's tongue and sometimes led to unwonted confidences. Both the *Conventus* of St. Augustine's, Canterbury, and that of the Augustinian Priory at Barnwell, near Cambridge, throw much light on phlebotomy as performed in English religious houses in the Middle Ages. The records of the practice go back to the seventh century; the Venerable Bede (A.D. 674-735) left a treatise on blood-letting. By the tenth century periodical bleeding was definitely accepted as a monastic custom, and it prevailed for several hundreds of years afterwards. In the discussion of the paper Sir D'Arcy Power observed that the dietetic indulgences which followed monastic blood-letting may have had the effect of causing an early need for further phlebotomy. He suggested also that the "unlucky days" must have been very convenient to the operator as an excuse for suppression or other mishaps following the operation. Dr. Singer concurred in this, remarking that no two monastic calendars agreed as to the "unlucky days," so that a misadventure could almost always be ascribed to supernatural influences. At the close of the meeting Mr. C. J. S. Thompson showed an interesting exhibit of blood-letting instruments and cupping appliances, which he had brought from the Wellcome Historical Medical Museum.

PUBLIC HEALTH IN RUSSIA.

We publish this week the third and concluding instalment of an article on public health in Russia by Dr. Haden Guest, who has recently visited that country. The article is undoubtedly tendentious, but this does not to any material extent diminish its interest. The interest lies in the picture drawn, with obvious sincerity, of the courage and resource with which the Russian people are themselves endeavouring to get the country into order, and of the kindly expert guidance given by the Russian medical profession. It had to face both epidemic and endemic disease of a kind and of an extent sufficient to appeal the stoutest

heart; very many of its members have given their lives in the attempt to prevent or remedy the consequences of famine and the ravages of disease. So far as epidemic diseases is concerned considerable success has been attained with the assistance of the Epidemic Commission of the League of Nations and the American Relief Association. The picture Dr. Haden Guest draws, while it contains many dark shadows, is encouraging, and its truth is corroborated in its main outlines by the experience of Professor Philip, formerly Estonian Foreign Minister, recently transmitted by the Riga correspondent of the *Times*. In his opinion the leaders of the revolution, theories which have long been obsolete in most other countries, are now obsolescent in Russia, where the people themselves are realizing that discipline is necessary to the comfort of the individual and the prosperity of a nation; he instances the greater attention now paid to street scavenging, but he admits that Russia has not yet become tranquil and happy, and says that "judged by our standards life is hard, notwithstanding that the requirements of the people have been reduced to a minimum." The new bourgeoisie and the new intelligentsia "have emerged from the struggle for existence hardened, and above all practical, people." This view is confirmed by what Dr. Haden Guest has to tell us about the schemes for improving the conditions of child life, and the preliminary steps which have been taken to deal with tuberculosis in schools. In sending the manuscript of his article he was good enough to accompany it by a number of photographs, but it was not thought that reproductions of them would be of interest to our readers, for a clinic in Russia is so like a clinic in Great Britain that they are only to be distinguished by the language in use. There is a great deal of human nature in man, and when we come down to fundamental things, such as the medical treatment of the ailing and sick, it is very much the same nature in Russia and in Great Britain.

THE STORAGE AND SUPPLY OF OXYGEN.

The Oxygen Research Committee, appointed in January, 1919, has presented a report on the work done down to the early part of this year. During the war investigations were begun under the War Office, the Aircraft Production Department, and other Government departments; in the summer of 1918 a special committee was set up to co-ordinate the work of the various departments as part of the general arrangements for dealing with the production and distribution of oxygen in this country. After the armistice there was a general feeling that the researches should be continued, and consequently an Oxygen Research Committee was appointed under the chairmanship of Professor J. F. Thorpe, D.Sc., F.R.S. It contained representatives of the War Office and of the Air Ministry, and a number of experienced workers in physiology and physics. The fundamental problem was to endeavour to furnish, especially for aeronautical, medical, and other scientific purposes, a more ready means than then existing for the utilization of the oxygen. The war committee had investigated the production of satisfactory light cylinders for compressed oxygen, but the question was of wider scope, since other gases had to be considered at the same time; it was therefore handed over to a Gas Cylinders Research Committee appointed in 1918, and in 1921 it recommended and specified lighter cylinders for commercial use. The Oxygen Research Committee, however, retained its interest in the problem in view of the fact that there is still an urgent need, for use in hospitals and for other special purposes, of cylinders even lighter than those recommended by the committee under the authority of H.M. Stationery Office, 1921.

The points which impress a visitor are the great care taken to get pure water, and a cress free from weeds, and to secure a fine growth by constant weeding, the use of artificial manure and the restocking of the beds with vigorous young growth.

At Mitcham Mrs. James grows green cress, which is marketed from April to September. Here there are about ten acres of beds, fed with water from the Wandle, a river which rises in the chalk hills. The green cress is cut when about six to seven inches above the water, so needs little subsequent trimming. The beds have to be constantly trimmed to prevent flowering and too coarse stems. The growth looked delightfully green, clean, and fresh, and one had no hesitation in chewing it on the spot. The beds here have a loamy bottom, but as the cress is not pulled this is no disadvantage from a cleanliness point of view. Amongst other cress beds which I visited were those at Croxley Hall Farm, Rickmansworth. Here there are about twenty acres of beds, fed with water from natural springs and artesian wells in the chalk. Mr. Sansom, the proprietor, grows brown cress in the winter and green in the summer, and supplies the North of England as far as Newcastle-on-Tyne. He has sent supplies to Scotland, but prefers to send to places where he can have the cress on sale within twenty-four hours of cutting.

From an agricultural point of view there is undoubtedly much land worth a nominal rent only which, if converted into cress beds, would be worth £15 to £20 an acre. All the beds which I have visited appear to be fed by rivers, springs, or wells from the chalk. I imagine limestone districts would be equally suitable. I think the encouragement of watercress growing is a matter worthy of consideration by our Ministry of Agriculture. I think also that the demand would increase if the public could be assured that the beds were inspected by some responsible authority. I need hardly point out that the inspection of watercress beds is not a difficult matter like the inspection of dairy farms. It is really only a side-show of rivers pollution inspection.

From a public health point of view watercress is a cheap green vegetable which, like lettuce, is eaten unspiced by cooking, but which, unlike lettuce, is available all the year round. Its more extended use may therefore be an appreciable help in remedying dietary errors caused by urbanization.

## DISCUSSION.

Dr. E. LEWYS-LLOYD (M.O.H. Merionethshire) recalled several instances showing the value attached to watercress by tradition in Wales and elsewhere.

Dr. R. D. SMEDLEY (M.O.H. West Sussex) said that watercress had lost favour in recent years, but had formerly been a much esteemed delicacy. It was still so regarded in parts of France, where it was grown and consumed on a very large scale. He considered it was of great importance to encourage the consumption of green uncooked vegetables, and agreed that watercress supplied a most valuable element in diet.

Dr. WHEATLEY (C.M.O. Shropshire) hoped that careful biological experiments would be made to determine the special value of watercress as opposed to ordinary green vegetables. General conclusions as to its value, whether past or present, were not sufficient in view of the possible risk of infection through eating watercress from polluted waters. This danger had been reported very fully by the late Sir Shirley Murphy, who had been able to trace quite definitely several cases of typhoid fever to infection from this source. On the other hand, if watercress could be produced in sufficient quantity and at a sufficiently cheap rate to provide a real supply of green food, and if it could be efficiently protected from infection, it would prove to be of real value. He thought Dr. Scurfield was to be congratulated on bringing the matter forward.

Dr. SCURFIELD, replying on the discussion, thanked the members of the Section for the interest they had shown in the subject. He considered increased use of raw green

vegetables to be a matter of real importance, and when he said inspection would be an easy matter he referred to regular cultivated beds, and not to odd sources of supply. His experience was that most people, including children, liked watercress. He mentioned the traditional properties of watercress, not because he believed in them all, but because of their historical interest. It was also his experience that much more watercress was eaten in France than in this country. Dr. Scurfield also read a letter addressed to the President of the Section (Dr. Mearns Fraser) describing how watercress could be profitably grown during the autumn and winter in an ordinary garden frame.

DISCUSSION ON THE EFFECT ON HEALTH OF  
SEWER AIR AND DRAIN AIR.

## OPENING PAPER

BY

FRED. E. WYNNE, M.B., D.P.H.,

M.O.H. Sheffield; Professor of Public Health, Sheffield University.

THERE is a tendency in sanitary practice, as in other forms of procedure, to become, as it were, crystallized, so that it fails to respond at once to changes in theory. A certain inertia is no doubt an advantage, as it gives time for the confirmation of truth and the elimination of fads.

It is, of course, always the duty of the sanitarian to ensure that his practice is, as far as possible, in accord with modern theory, but the strictest scrutiny is more particularly necessary in these days when public health estimates, both national and local, have had to be cut to the quick. It is also most important that we should exercise the same care in making demands on property owners that we do in administering the public funds at our disposal, since every pound unnecessarily spent lessens the purchasing power of the nation, and so contributes to poverty and unemployment—the main causes of public ill health.

In view of the appalling sanitary conditions which had been allowed to develop prior to the passing of the Public Health Act of 1875 it was natural and right that the attention of our predecessors should be largely concentrated on the abatement of nuisances generally, and especially the efficient removal of excreta from dwellings by properly constructed sewers. This was in accord with the principle that all life is destroyed by the accumulation of its own products, which applies to communities just as it does to individuals. The improvement in public health resulting from these measures very soon became apparent, but the work then inaugurated is even now far from complete.

As long as there are slums, unpaved yards, privy middens, and open ashpits left in our towns, I believe that it remains the first duty of the sanitary authority to proceed with their elimination, and that the energies of medical officers in particular should not be entirely diverted to the more fashionable pastime of dealing with the individual and prolonging the lives very often of the least desirable elements in society.

While the principles of the Public Health Act were thus absolutely sound, and its effects of inestimable benefit, it was not unnatural in those days of imperfectly understood etiology of disease—when, for instance, Murchison's pythogenic theory of typhoid fever was still an article of faith—that defective drains and sewers came to be regarded as one of the principal factors, if not actually the principal factor, in the causation of epidemic and infectious diseases.

Typhoid fever and diphtheria in especial were attributed to faulty drainage, and this association still lingers in many minds. Modern views of the etiology of these diseases make it certain that the causation of either of them by the escape of drain or sewer air into the dwelling house is a remote improbability, if, indeed, it is even a possibility.

Nevertheless it seemed intolerable at one time to abandon the idea that faulty drains had an important influence on the incidence of these diseases, to admit that all our elaborate precautions against the reflux of air and gases from the sewer to the drain, or from the drain to the

WE are informed as we go to press that the interim returns from a considerable number of Panel Committees have been received, and that an analysis of them shows that the resignations tendered in these areas in response to the advice of the Insurance Acts Committee exceeded the 66.6 per cent. required by the Committee. The Committee determined that it would not direct any resignations to be sent in unless two-thirds of the medical practitioners on the panel decided to resign. From information in the possession of the Committee it is confidently anticipated that the required percentage will be considerably exceeded before October 31st, the last day on which resignations can be sent in, as two months' notice must be given. In some districts 100 per cent. of the medical practitioners have already sent in their resignations to the secretaries of their Panel Committees.

#### FIRM ATTITUDE OF PANEL PRACTITIONERS.

THE *Cape Times* of September 13th contains an interesting "authorized" statement as to the results of the investigations which Professor Kleine and Dr. Fischer have just concluded in Rhodesia on the action of Bayer 205 in trypanosomal diseases. A previous note on their work was published in the *British Medical Journal*, January, 1923, page 35. About 220 patients in various stages of sleeping sickness were treated. Patients whose central nervous system was unaffected were, it is stated, cured after four injections (subcutaneous or intravenous) of 1 gram each. After the first or second injection the fever abated and the swelling of the glands began to go down. The efficacy of the treatment was so marked that natives came to seek it in large numbers. In cases where the brain was affected or paralysis had set in a longer course of treatment was required, but details as to the ultimate effects of such treatment have not been published. The action of Bayer 205 on ngana, a trypanosomal disease of cattle, was not so satisfactory, and its value in this disease is uncertain. It is promised that full details of the researches shall be published later.

WE publish this week a review of a book on gastro-enteroposia on the principle that a good book should no suffer on account of the indiscretion of the publishers, but in respect of the action of Messrs. D. Appleton and Co., New York, in respect of the five monographs of which Dr. Coffey's is one, as indiscreet. The monographs deal with such unrelated subjects as traumatic shock, the reconstruction surgery of the upper extremity, gastro-entereostomy, the transplantation of tissues, the surgery of the spleen, and physiotherapy. The publishers, however, declined to sell each monograph separately, and ask the sum of £6 5s. for the five volumes, which are issued in set only. This is a most undesirable innovation, and we decided that at a meeting of the Library Committee of the Royal Society of Medicine, held on October 25th, it was decided that the Honorary Librarian should write to the publishers to say that the purchase of the monographs would be considered when the restriction had been withdrawn. The Committee regarded the plan as a bad precedent which should not be allowed to pass.

WE may remind our readers that the Semon lecture will be delivered at the Royal Society of Medicine (1, Wimpole Street, W.) on Thursday next, November 1st, at 5 p.m., by Dr. A. Logan Turner, lecturer on diseases of the throat and ear in the University of Edinburgh. His lecture will be a plea for the advancement of laryngology and otology. Students of the University of London at others interested in the subject are invited to attend.

were caused by incomplete convalescence from ailments in childhood, and there was a great need for an increased number of inexpensive convalescent homes. The annual dinner of the society was held in the evening, when the Minister of Health proposed the toast of the society, which, he said, was founded on a small scale in 1875, but now numbered over 1,600 members. The introduction of modern sanitary measures was due in large part to the advocacy of medical officers of health, and they had had a great share in the clearing of the slums. Looking to the future he expressed the hope that they would assist him in a campaign he proposed to institute for the construction of new arterial roads. People followed roads if they afforded ready means of transport, and he hoped that factories would be established on these roads, so that the workers might live in healthy surroundings. Dr. Naylor Barlow, in his reply, criticized the recent action of the General Medical Council in revising the curriculum for the diploma in public health, with the result that future candidates would have to spend two years on the special course after they had taken a registrable medical diploma. In proposing the health of the guests Dr. F. E. Fremantle, M.P., succeeded in the difficult task of mentioning, with a graceful adjective, all the principal guests. In the course of his remarks Dr. Fremantle spoke of Lord Riddell as the dozen of journalists, an epithet which seemed a little to nettie Lord Riddell, who, in his reply, appeared to question its correctness. However, he told several good stories, and promised to make another collection for next year. Sir Square Spriggs, who also replied to the toast of the guests, spoke of the growing complexity of medicine and the difficulties it created for the editor of a medical journal—difficulties which, he said, would be insuperable but for the assistance readily given by members of the profession having knowledge of special subjects. Among other guests present were the President of the Royal College of Physicians (Sir Humphry Rolleston), Sir George Newman, Sir Arthur Robinson, K.C.B., Sir William Hamer, Lady Mary, Dr. Wallace Henry (Chairman of Representative Meetings, British Medical Association), Dr. Alfred Cox, Medical Secretary, and Sir Dawson Williams, Editor of the *British Medical Journal*. The toast of the President was given by Sir Benjamin Johnson, High Sheriff of Lancashire, and suitably acknowledged by Dr. Naylor Barlow.

#### TREATMENT OF TUBERCULOSIS BY THE SPALINGNER METHOD.

ACCORDING to what appears to be an authoritative communication, published in the *Times* of October 17th, a meeting was held recently in London at the invitation of Baron Henri de Rothschild, who is a member of the medical profession, to consider what steps should be taken to provide a fund to prevent the closure of M. Spalinger's laboratory at Carouge, near Geneva. Such particulars of M. Spalinger's methods and of the production of his vaccines and serums as were available were given in two articles published in the *British Medical Journal* of May 12th (p. 830) and June 2nd (p. 928). Dr. Leonard Williams recently reported (September 22nd, p. 519) a series of cases of tuberculosis he had observed under treatment by the Spalinger method. It is stated that the meeting decided shortly to issue to members of the medical profession a pamphlet giving a history of M. Spalinger's work accompanied by medical evidence and clinical details. Eventually it is proposed to make an appeal for subscriptions to meet the expenses already incurred by M. Spalinger and to enable him to continue his work. It is reported that on October 15th the Lancashire Insurance Committee set aside a sum of £1,000 for the supply of

Haldane is there quoted as giving his opinion that the theory of sewer-air infection was based on worthless evidence, that as a general rule illness was put down to sewer air if the cause was unknown, and that he was even very suspicious of the theory that sewer air, apart from its smell, can be a predisposing cause of disease.

These are not new facts. They have been known and admitted for years, yet we seem to lack courage to act on them. We retain by-laws which require the provision of intercepting traps often at a considerable cost; we insist on systems of sewer ventilation which often create far more nuisance than the imaginary ones they are designed to prevent; and if we succeed in getting smoke, under a pressure to which drain air is never subjected, to make its way through some minute flaw, we call upon the owners of the property to relay drains at a cost which may be almost ruinous in these difficult and harassing days.

It took a generation to educate the public into a horror of insanitary conditions, and it is perhaps natural that there should be some reluctance to teaching anything that might weaken that dread, perhaps also a little timidity in opposing tradition and orthodoxy. But now that experience has shown us which are the really useful and economic lines of sanitary reform, I think it is essentially our duty to point these out and insist on their being put into operation, while rigidly preventing unnecessary expenditure on what we now know to be merely the bogies of an outworn creed.

## DISCUSSION.

(The chair was taken by Dr. LOCKHART STEPHENS.)

Dr. MEARNS FRASER (M.O.H. Portsmouth) said he thought it would be difficult to draw the line as to when a drain became so defective as to be dangerous, and he was personally inclined to continue on the safe side. From the practical point of view he found that defects or alleged defects in drains were very often reported by private medical practitioners, and if they took the line of refusing to act on such information it might involve them in controversies with the general practitioner. He did not quite appreciate the distinction drawn by Dr. Wynne between soil pollution and air pollution. It was often believed that food poisoning might be caused by contamination of food-stuffs by drain air. He emphasized the fact that defective and untrapped drains might serve as rat-runs and in this way become a danger and a nuisance. He felt it was probable that the danger of inhaling sewer or drain air was exaggerated, but that, on the other hand, it might be dangerous to assert its positive harmlessness.

Mr. WYNTER BLYTH, D.Sc., F.I.C., in a very interesting communication, criticized much of the experimental work which had been done in connexion with the bacteriology of sewer air, which, he said, had in many cases been carried out by people who were quite vague as to the chemico-physical problems with which they were confronted. Sewage, he said, was a variable mixture of inorganic salts and organic compounds both in solution and suspension, and a large part of the suspended matter was in the colloidal state. House sewage tended on agitation to form froth and bubbles. The gases composing the air of sewers and drains did not differ materially from ordinary air except for variable quantities of the gases of decomposition whose concentration would be more or less proportional to the state of ventilation. Apart from the physiological or psychological effects of inhaling evil-smelling gases one would accordingly expect no ill results from such inhalation provided the air were free from micro-organisms. The main point therefore appeared to be to inquire to what extent and under what conditions organisms could be carried from sewage to sewer air, and how long they could remain in suspension in the air and retain their vitality. There was no doubt that organisms could be thrown into the air, not only by splashing but by the bursting of bubbles, and the blowing down of foam. Horrocks, in his

experiments published in the *Journal of the Royal Sanitary Institute* (No. XXVIII), had obtained a positive result in a plate exposed, in one case 9 ft. and in another 11½ ft., above the surface of the sewage, but unfortunately published no data as to the draught in his experimental pipes, the conditions under which the organisms were ejected, or the condition in which they were when so ejected. With a view to determining some of these factors he had himself recently conducted certain experiments which showed that the pressure inside a bubble was maintained by the surface tension of the liquid—the higher that tension the greater the pressure per unit area of the surface of the bubble. In accordance with this law he had obtained a positive result with plates exposed at 9 inches above ordinary tap-water containing *B. typhosus*, but the result was negative at one foot above the surface. In another experiment under identical conditions, but with soap solution instead of water, growths were obtained at 4 inches, but not at 6 inches. Further experiments had been made to determine the distribution of organisms in frothing solutions of gelatin and soap. The results were not so far conclusive, but he felt justified in saying that there was evidence of some concentration of organisms in the froth—that was to say, the organisms were not driven out from the air-liquid interface. It was proved that the thinnest bubble—that is, one with a film of about 0.0017  $\mu$  in thickness—could carry a micro-organism with a diameter some 17,000 times greater than this. When a bubble breaks there is no "explosion," but the film, as it were, "flaps back" at a rate of seventy-two miles per hour, and it is this force which ejects the comparatively enormous organism. Absorption of liquid by the organism is one of the factors in determining its convection by light currents of air, and such absorption is minimized if the organism has been in contact with grease, which is one example of the complexity of the problem. However, it was found by experiments with *B. prodigiosus* that the maximum time taken to fall through 100 cm. when discharged from a bubble of soap solution was one minute, and when discharged from a bubble of gelatin solution forty-five seconds. By applying Stokes's law the radius of the particle of liquid containing the organism is found to be in the first case 11.7  $\mu$ , and in the second case 15.8  $\mu$ . The volume of the globule of water and organism to that of the naked organism is therefore about 1,000 to 1. Nevertheless these particles are small enough to be carried considerable distances by low velocity currents of air, as much as 6 ft. in a draught of only 30 ft. per minute.

Dr. SCURFIELD (late M.O.H. Sheffield) mentioned a personal experience of residence for a considerable time in a house in which eventually smells called attention to the drainage, which was found to be profoundly defective. He could not say that any of the occupants had experienced any ill results in regard to their health. At the same time he thought it would be dangerous to ignore serious defects, as if a drain were pervious an accumulation of sewage in the foundations might be the first indication of a blocked drain. He had advised health committees for twenty years that diphtheria could not be caused by drain air, but that inhalation of such air might lower the general health and therefore the resistance to infection. He asked, If drain air was innocuous why were the effluvia from privy middens dangerous? He hoped that further research would be carried out by Dr. Wynter Blyth on the very interesting lines of his paper, as before any alterations in by-laws could be adopted it would be necessary to convince the architects of the Ministry of Health.

Dr. G. H. PEARCE (M.O.H. Batley) was of opinion that all defects in drains should certainly be made good and no second-rate work permitted, but the findings of the Departmental Committee on intercepting traps had greatly modified their ideas as to the effects of sewer air. He found that typhoid fever was mostly spread by flies and the consumption of shellfish, and diphtheria by carriers.

view of the high percentage of CO in modern gas. He thought it was not generally realized how common this form of pollution of air was, and Dr. Hazleton's suggestion for its remedy was as valuable as it was simple. He thought it not unlikely that conditions commonly attributed to sewer gas were due to this cause.

Dr. SCURFIELD agreed that Dr. Hazleton had called attention to a matter of very great importance in connexion with the public health. The danger of leakages of gas was increased by the fact that many persons were very insensitive to its smell, and so might remain unaware of quite poisonous amounts in the air they breathed.

Several other speakers thanked Dr. Hazleton for calling attention to a matter of such practical importance, and hoped that his method of prevention would in time become general.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### ASTHMA DUE TO INSECT POWDER.

Mrs. D., an apparently healthy woman of 24, consulted one of us (J. R. G.) on August 10th, when she was found to be suffering from a severe attack of asthma.

Her history was that on August 7th, at about 6 p.m., she bought a tin of a well known brand of insect powder and sprinkled some of it on her bed, on which a dog had been lying. In about half an hour she noticed that her eyes were watering, sore, and itchy. When in bed that night she had the first stages of an asthmatic attack. She could not "get her breath" and there was a "catch" in breathing. The next day she had little to complain of, but that evening and night she felt worse. The attack was most severe on the following night (August 9th). When seen on August 10th the signs and symptoms were those of severe bronchial asthma. Under appropriate treatment she gradually improved, and at the end of a week was quite comfortable during the day and only slightly "wheezy" at night.

Only once previously had she suffered from asthma. That attack came on about a year before when she was staying in the country on holiday. The previous occupant of her bed had been a lady who had three dogs, and before Mrs. D. arrived the landlady had made free use of insect powder on the bed. The attack developed the first night Mrs. D. spent in the bed, and, after three days of misery, she returned home and was completely well within a week.

The only one of her relatives who suffers from asthma is a maternal aunt who has been a frequent victim from her girlhood. In her case no connexion between attacks and either food or environment has been noticed.

In order to confirm or rebut Mrs. D.'s conviction that the powder was the cause of her attack, her sensitiveness to it was tested by the other recorder (J. W. B.). A few superficial scratches were made on each forearm. The abraded surface on the right arm was rubbed with carbolic saline, that on the left with a suspension of the powder in the same solution. Within five minutes there was a marked difference between the two arms. The scratched surface on the right was surrounded by a slightly hyperaemic zone, but that on the left forearm showed as a raised white wheal in the centre of a bright red patch. The reagents were then washed off with salt solution. The condition was kept under observation for a further ten minutes, when the visible and palpable wheal was much more marked and the red zone larger. The subject stated that it was rather itchy. When seen six hours later there was but little difference between the arms, and Mrs. D. said that the swelling had almost completely disappeared within an hour from the commencement of the experiment. In view of the very rapid and marked skin reaction there can be little doubt that Mrs. D. was very sensitive to the powder and that it was the cause of her attack of asthma. No attempt was made to immunize her against the substance as it is one fairly easy to avoid. Since she has only suffered from these two asthmatic attacks it seems probable that her range of sensitiveness is small. She was not tested with any other substance.

The makers of the powder did not reply to my question

as to its composition, but it apparently consists, in whole or part, of pyrethrum, and it is probable that this substance was the responsible agent.

The case seems worth recording since, so far as we have been able to discover, no similar case has been noted before.

#### SYPHILITIC STRICTURE OF THE SMALL INTESTINE.

The following case of severe generalized syphilis, with syphilitic stricture of the small intestine, causing intestinal obstruction and resulting in death, presents some interesting features worthy of record.

A man, aged 45, was admitted to hospital on December 6th, 1922, complaining of severe gastralgia which began about a week earlier. He had been troubled by frequent attacks of indigestion for twelve years, with occasional vomiting. He had served as a regular soldier in India, where he had slight malaria, and he had been a rather heavy drinker for many years. For the most part, however, his health had been good. During the war he served in Salonica, where he got a fresh infection with malaria in 1917, but was not seriously ill, and the last attack of malaria was in 1921. He had iritis in the left eye in 1915.

On admission he was pale and thin, and the lymphatic glands on both sides of the neck were enlarged and hard. There were no abnormal physical signs in the heart or lungs. The left pupil was "pin-point" and fixed, apparently due to the old iritis. The right pupil was normal in size and reacted slowly to light, and more actively to accommodation. Deep reflexes and sensation were normal. There was slight tenderness over the pylorus, but the abdomen was difficult to palpate, as the recti muscles were rigid. He vomited occasionally, even when on a diet of bread, milk, and pudding. The bowels tended to be constipated. An Ewald test meal, given on December 10th, revealed a total absence of free HCl, and a total acidity of 10—that is, there was a complete achylia gastrica. No Boas-Oppler bacilli were found. On December 15th the Wassermann reaction of the blood was reported positive. X-ray examination showed the stomach to be normal in size and position, and that it emptied itself in five and a half hours. There was no evidence of narrowed pylorus or tumour formation. The patient was put on dilute hydrochloric acid with pepsin, and on mercury and potassium iodide. At the end of December intravenous injections of 0.3 gram novarsenobillon were begun, but after each there was so decided an exacerbation of pain in the stomach that the injections were stopped after the third.

He did not improve, but became sick more frequently, so that at first medicines and then food by the stomach had to be stopped, and bowel feeding was resorted to. He became more emaciated and the sickness continued. Early in February, 1923, he had a twitching of the left eye which lasted for three minutes, and he was dazed for some time afterwards.

The patient was transferred to the surgical department on February 17th, as a last resort. He was then very weak and emaciated, but the appearance of the abdomen was striking. It was well and uniformly filled and firm, in marked contrast to the extreme wasting of the rest of the body. With the object of introducing peptonized milk directly into the small intestine an incision was made in the epigastrium, and a loop of small bowel was picked out. This loop presented a stricture, about 3/4 inch in length and 1/4 inch in external diameter, which was very firm, and avascular. On both sides of this stricture the bowel rapidly expanded to fully an inch external diameter. The fullness of the abdomen was largely due to great infiltration of mesenteric glands and retroperitoneal tissues. An enterostomy was rapidly performed below the stricture, and the patient fed; he was also stimulated with radiant heat, pituitary extract, etc. The temperature, which had fallen to 96°, rose almost to normal, and for a time he retained nutrient injections and salines, and slept well. Three days later, however, he died.

Post mortem, in addition to the retroperitoneal masses, masses were found in the liver and the upper pole of the left kidney, and large firm masses in the mediastinum. Microscopical examination showed these masses to be gummatous. The stricture of the intestine was situated in the jejunum, and, on section, the very narrow lumen was found to be neatly closed by a grape seed which acted as a ball valve, the little projection at one end of the seed entering the stricture and acting as the valve stem or guide. The thick walls of the stricture showed gummatous infiltration.

We are indebted to Drs. E. Currie and M. Davidson, resident medical officers, for the use of notes made upon this case.

W. K. ANDERSON, M.B., Ch.B.,  
Physician,

Surgeon,  
Eastern District Hospital, Glasgow.

Clinical Laboratories at London Medical Hospitals.

At most of the mental hospitals under the control of the London County Council clinical laboratories exist, but the Mental Hospitals Committee is now proposing that a clinical laboratory shall be established at every one, the equipment of them all to be standardized, and arrangements to be made for the co-ordination of their work with that undertaken at the central pathological laboratory at the Maudsley Hospital. This proposal will entail an estimated expenditure for all the hospitals together of £710 initially, and £550 a year for maintenance. A new position of laboratory assistant is to be created at the mental hospitals, at a rate of pay equivalent to that of a mental chief charge nurse. This laboratory assistant, in addition to performing such duties as are required in the laboratory, will take over the duties of mortuary or post-mortem attendant, now performed by one of the male nurses.

Post-Graduate Courses in London.

The programme of special courses arranged by the Fellowship of Medicine and Post-Graduate Medical Association covers a wide range of subjects, beginning with a fortnight's course in general medicine and surgery at the Royal Northern Hospital, in conjunction with the Central London Ophthalmic Hospital, North-Eastern Fever Hospital, and the Royal Chest Hospital. Clinical demonstrations in the various departments will be given each day from 10.30 a.m. to 4.30 p.m. Also beginning on November 5th and continuing throughout the month there will be a course in gynaecology at the Chelsea Hospital for Women. Lectures will be given by members of the staff in psychological medicine has been arranged at the Maudsley Hospital, Denmark Hill, and will consist of lectures and demonstrations on the psychoneuroses, the practical aspect of mental deficiency, the pathology of mental diseases, clinical psychiatry, and crime and insanity. Also at the London Lock Hospital (Dean Street and Harrow Road) a comprehensive course of lectures and clinical demonstrations on venereal diseases will be given from November 5th to 29th. A lecture on some aspect of the subject will be given each day, supplemented by clinical work in the wards and out-patient department. From November 18th to December 15th a practical course in ophthalmology will be given at the Royal Westminster Hospital. In addition to clinical instruction every afternoon from 2 o'clock, a practical fundus class and special demonstrations in medical ophthalmology and methods of examination will be given three times a week at 10 a.m. Beginning on Monday next (October 29th) a two weeks' course in dermatology will be given at the Hospital for Diseases of the Skin, Blackfriars, consisting of clinical instruction every afternoon from 2.30, with special demonstrations on selected cases. Further particulars and copies of the syllabus of any of these courses will be forwarded on application to the Secretary to the Fellowship of Medicine at 1, Wimpole Street, W. 1.

The Public Health Committee of the London County Council submitted to that body on October 23rd a report of the recent outbreak of small-pox in London. There were 18 cases (2 fatal), of which 11 occurred in the County of London and 7 in the extra-metropolitan districts. Attention was first directed to the appearance of small-pox on September 7th by the medical officer of health for a South London borough, who discovered a case in a girl employed as a chambermaid at a hotel in Central London. This girl had waited upon a lady visitor from Spain who had been ill at the hotel from August 15th to 19th, with what was thought, without medical advice, to be influenza, with spots attributed by her to fish poisoning. Four other cases were discovered within twenty-four hours in widely separated districts, and contact with the original case from Spain could be traced in two of these cases. The Spanish visitor herself was traced to an address in an out-county suburb, where she was found to be recovering from a mild attack of small-pox, but she had infected an adult relative, who was suffering from a severe attack, and another relative with

The recent outbreak of small-pox in London.

Scotland.

Cameron Prize Lectures in Edinburgh.

The recipient of the Cameron Prize for 1923 at the University of Edinburgh, Professor J. J. R. Macleod, M.B., F.R.S., Professor of Physiology in the University of Toronto, delivered the two Cameron Prize Lectures in the anatomy classroom on October 16th and 17th. Principal Sir Alfred Ewing in introducing the lecturer stated that the Cameron Prize was the highest honour the University of Edinburgh had bestowed on work in practical therapeutics, being awarded to anyone who in the preceding years was considered to have made an important and valuable discovery in that subject. Professor Macleod had played a most distinguished part in the development of treatment of diabetes by insulin—a treatment which, if it could not be said to effect a cure, had at least brought restoration and hope to many sufferers. The discovery had focused the attention of the medical and scientific world upon Professor Macleod's laboratory in Toronto, though the credit was of course shared with co-workers. The discovery of the substance had been made there by Dr. Banting, who, along with Mr. Best, had shown that it could be prepared by using partially degenerated pancreas; and this fundamental discovery had been developed by Professor Macleod and his co-workers, especially by Mr. Best and Professor Collip. Professor Macleod's lecture dealt with the "Nature of Control of the Metabolism of Carbohydrates in the Animal Body." It had been supposed, he said, for many years that carbohydrate metabolism was regulated by an internal secretion of the pancreas to which Sir Edward Sharpey Schaffer had actually given the name of "insulin," but it had not been possible to isolate that material until the researches of Dr. Banting and Mr. Best. The method by which insulin could be prepared in adequate quantities from adult ox pancreas was devised mainly by Professor Collip. The use of the preparation had opened up a large field of investigation in metabolism, not only of carbohydrates but of fats and proteins. The address Professor Macleod delivered to the International Congress of Physiology in Edinburgh, in which he reviewed the whole subject, was published in the British Medical Journal of August 4th (p. 165).

The delivery of the hundredth annual course of Macleod Lectures in Edinburgh was made the occasion of a general dinner in the hall of the Royal College of Physicians on October 16th, when Professor George M. Robertson, physician superintendent of the Royal Asylum, Edinburgh, was in the chair and delivered an address.

The historical narrative of the events connected with these lectures given by Dr. Blackhall-McLaurin in his centenary lecture was most appropriately with an account of the foundation of the Royal Hospital at Edinburgh, which is in itself a romantic story. It was founded by Dr. Andrew Duncan, Professor of Medicine at Edinburgh, who was

## TREATMENT OF PUERPERAL SEPSIS.

A MEETING of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine was held on October 4th, with Dr. CUTHBERT LOCKYER, President, in the chair, when Mr. GORDON LUKER read a paper on the treatment of puerperal sepsis by a combination of antistreptococcal serum with intravenous and intramuscular injections of quinine bishydrochloride. This method had been used by him in a series of cases of puerperal septicaemia during the past twelve months with extremely satisfactory results. Thirty-six cases of puerperal septicaemia were admitted to the London Hospital in the year under observation, of which twenty-four had been treated by this method, with only two deaths. Both of the patients who died had suffered from toxæmia of pregnancy and antepartum pyrexia. Previously, the mortality among hospital cases had been about 35 per cent. Up to the present small doses only of quinine had been given, the maximum being 5 grains. The paper was illustrated by charts of all the cases treated.

Dr. EVERARD WILLIAMS showed a specimen of adenomyoma occurring in a bicornuate uterus. The subject from whom the specimen was obtained was a single woman, aged 31, who had absolute amenorrhoea, with severe abdominal pains each month. In each side of the pelvis, situated at the junction of the Fallopian tube with the uterine horn, was a small solid tumour which on section was found to be adenomyoma.

Mr. W. GILLIATT described a condition in which a patient had had a placenta prævia in four successive pregnancies. The patient had been pregnant only four times and the children had all been male; two of them were now alive and well, and two were stillborn. No abnormality of the pelvic organs could be detected during pregnancy, in labour, or in the intervals between the pregnancies. There were only two other cases recorded in the literature in which placenta prævia had occurred more than once in the same patient.

Drs. H. WILLIAMSON and G. F. ABERCROMBIE communicated a note on a case of inversion of the uterus caused by a squamous-celled carcinoma of the fundus. The inverted uterus was treated by the application of thirteen needles containing radium bromide so as to irradiate the whole of the malignant tissue equally. The uterus was removed by abdominal panhysterectomy, and the patient did well.

## CLINICAL MANIFESTATIONS OF CEREBRAL TUMOUR.

THE opening meeting of the Royal Medico-Chirurgical Society of Glasgow was held on October 5th, when an address was delivered by Dr. GORDON M. HOLMES, entitled "The clinical manifestations of cerebral tumour."

Employing the term "tumour" in its widest sense, Dr. HOLMES said that cerebral tumours were much more common than they were generally believed to be. The clinical manifestations, which were often complex, and which might vary from time to time in form and severity, might be considered under two headings: (1) general, due to increased intracranial pressure, on which the diagnosis of the actual presence of a tumour depended; and (2) local, due to the pressure of the tumour on the neighbouring parts, on which the diagnosis of the site of the tumour depended. After referring to the causes of the increase in intracranial pressure, Dr. HOLMES considered in detail the cardinal symptoms arising therefrom—namely, headache, vomiting, and optic neuritis or papilloedema. The headache, due to congestion of the vessels, occurred as a rule in the morning and was usually referred to the frontal region—"behind the eyes"—though occasionally, as in cerebellar tumours, the pain was chiefly occipital. The vomiting, which bore no relation to the ingestion of food or to the condition of the stomach, was frequently accompanied or preceded by nausea (contrary to what was usually stated in textbooks) and was almost invariably associated with the morning headache. Optic neuritis, a most valuable positive sign and generally present in cerebellar and

mid-brain tumours, was unfortunately often absent in early cases, especially in tumours in the region of the pons and basal ganglia. It was important to distinguish between true papilloedema and such conditions as neuro-retinitis of arterial or renal disease, or pseudo-papillitis. Of the remaining general symptoms, a slow pulse rate was not of great significance; true vertigo, usually a local symptom in tumours of the posterior fossa of the skull, was comparatively rare; mental symptoms, though important, were often misinterpreted and attributed to primary mental disease or general paralysis of the insane. While none of these general symptoms was constant, and none, except, perhaps, papilloedema, was pathognomonic, they were rarely absent altogether, except in such cases as a slow-growing tumour where the intracranial pressure was not increased or the brain had time to adapt itself to the increased pressure, or in cases where there was no interference with the circulation of cerebro-spinal fluid. With regard to the local symptoms of cerebral tumour, which might take the form of either paralytic or irritative phenomena, the important points to note were the slow onset and the progressive and extending development to surrounding areas. Sudden and irregular exacerbation or diminution in the severity of the symptoms, both general and local, were not uncommon and were due to such causes as circulatory disturbances, interference with the flow of cerebro-spinal fluid, inflammation and oedema, haemorrhages, central softening of the tumour, and cyst formation. Very rarely there was a history of an acute or subacute onset—for example, in some of the cases of the infective granulomata—but careful questioning usually elicited slight premonitory symptoms.

Dr. Gordon Holmes then discussed briefly the differential diagnosis, including such conditions as cerebral degenerations, general paralysis of the insane, hydrocephalus, renal disease, and arterio-sclerotic disease. Of the accessory aids to diagnosis, such as radiography, ventrilo-graphy, or pneumography, and lumbar puncture, little real help was to be expected, and, in some cases, such information as they did provide was not commensurate with the risk of their employment. A decompression operation, while it relieved acute symptoms, often prevented any further chance of accurate localization, which, after all, was secondary only to the early recognition of its clinical manifestations in the diagnosis and treatment of cerebral tumour.

## INSULIN IN ADVANCED DIABETES.

A MEETING of the Brighton and Sussex Medico-Chirurgical Society was held on October 4th, 1923, with Dr. ELIOT CURWEN, President, in the chair, when Dr. R. SANDERSON read a paper on the effect of insulin in advanced cases of diabetes. He said that whatever may be the benefits conferred upon the diabetic by insulin, there seemed little doubt that it bade fair to bring many practitioners to a premature grave, so multitudinous, bewildering, and worrying were the problems involved. It was in the hope of minimizing the extent of this fatal toll upon his fellow men that Dr. Sanderson gave his experiences. We were, he said, to a large extent ignorant of the biochemistry of the metabolism of ingested food; we knew more than we did a few years ago, but there were large gaps in our knowledge. We knew that diabetes mellitus was not a disease connected with carbohydrate metabolism only, though this was its most obvious symptom, but that it was concerned also with the defective metabolism both of fats and proteins; it was a disease affecting metabolism generally. Dr. Sanderson then quoted Professor Macleod on the point that the metabolism of carbohydrates did not proceed independently, for in the chain of processes which preceded the final oxidation of glucose some substance was formed which was also intermediary in the metabolism of the other proximate principles of food—namely, fats and proteins. The metabolism of the three proximate principles therefore was closely interwoven so that when anything occurred to interfere with that of one of them some change was likely to occur in the others. The paper was discussed by Dr. BROADBENT.

interest. It looks, one might say, as though all the life-energy were ultimately seeking the subject, thus offering a constant hindrance to any overpowering influence on the part of the object."

In a series of fascinating chapters Jung shows how these two opposed types have influenced religious thought, art, science, and philosophy; he shows also how they have been recognized by thinkers under different names. Heine's enthusiastic mystical Platonic natures, and the practical, ordering Aristotelian natures; Blake's devouring and prolific types; James's tender-minded and tough-minded; Nietzsche's fundamental pair of opposites—the Apollonian and Dionysian; Oswald's classic and romantic types; and Jordan's more impassioned and less impassioned—all these correspond more or less closely to the introvert and extravert. Individuals in each of these groups naturally show considerable differences, and Jung divides the introverted and extraverted types into thinking, feeling, sensation, and intuitive function-types according to which of these functions has the principal share in an individual's orientation to life. This method of discrimination undoubtedly provides a useful scheme in which to include the infinite variations of attitude, and the outline given of the various types is obviously the work of an observer of profound psychological insight.

With these two contrasting types as a basis Jung proceeds to develop his psychological views. His psychology is complex and his exposition of it sometimes a little obscure; it has but few points of contact with the psychology of the textbooks, and the author frankly repudiates the possibility of understanding life or personality from the mechanistic standpoint. There is much in this book inviting comment, but we may perhaps remark more especially upon the complete inability of the introvert and extravert to understand or appreciate one another. James thoroughly appreciated the significance of this "clash of temperaments" in the sphere of philosophy; and in describing the "tender-minded" rationalist and the "tough-minded" empiricist he recognized the prejudices which are mutually cherished by the two types: "They have a low opinion of each other. . . . the tough think of the tender as sentimentalists and soft-heads. The tender feel the tough to be unrefined, callous and brutal. Each type believes the other to be inferior to itself." It is largely Jung's aim to show that "though strife and misunderstandings are, assuredly, constant requisites for the trago-comedy of human life . . . a basis for the adjustment of conflicting views could be found in the recognition of types of attitude, not however of the mere existence of these types, but also of the fact that every man is so imprisoned in his type that he is simply incapable of a complete understanding of another standpoint." It is not only in the high altitudes of philosophic thought that misunderstandings arise, however, but in our daily contacts with our fellows. Jung emphasizes this point in simple language in commenting upon Jordan's description of the extraverted man. He points out that the pitiless severity of Jordan's description shows him to be on the side of the introvert, and then in an illuminating passage indicates how such a lack of benevolence arises. This passage we will quote in full, because it reveals what is Jung's basic psychological position:

"It is certainly true that the extravert, if he has nothing to say, may find it necessary for a window to be opened or shut. But who has remarked it? Who is essentially struck by it? Only the man who is trying to give an account of the possible grounds and intentions of such an action, one therefore who reflects, dissects, and reconstructs, while for everyone else this little stir is altogether dissolved in the general bustle of life, without offering an invitation to any ulterior deduction. But it is just in this way that the psychology of the extravert reveals itself: it belongs to the occurrences of daily human life, and it signifies nothing more, either above or below. But the man who reflects, sees further and—as far as the actual life is concerned—sees crooked, although his vision is sound enough as regards the unconscious background. He does not see the positive man, but only his shadow." And the shadow admits the justice of the criticism, to the prejudice of the conscious positive human being." Here would seem to be an important truth on which we should do well to ponder. When the extravert opens or shuts the window we judge the man wrongly and fail to understand him if we say, "He always likes to be in the

limelight" (unconscious motive); our judgement is more true if we say, "He always does the right thing" (conscious purpose).

Jung's teaching must be understood as a reaction against the present tendency of psychologists to preoccupy themselves with unconscious motives and to ignore the existence of conscious aims. His primary classification of humanity into types, differentiated by the direction of their interest, gives a new orientation to psychology; it deflects the attention from origins to aims, from causes to ends. Jung points out that in daily life we instinctively view a man's action from the purposive standpoint; we are not interested so much in the motives or causes of an action, but rather in what the man intends by it, what are his aims and purposes, what he hopes to achieve by it. He feels that a scientific psychology must take this fact into account and not rely exclusively on the causal standpoint. Professor J. B. Baillie has picturesquely said that in the light of science "man is viewed as the most prominent marionette in the mechanism of nature." This is not Jung's view. For him man is not a mere puppet under the control of forces alien to himself, but a living subject, working out his own destinies according to the limitations of his peculiar type.

H. DEVINE.

## DISEASES OF RECTUM AND COLON.

MR. LOCKHART-MUMMERY has done well in revising his books on diseases of the rectum and of the colon respectively to combine them into one volume under the title *Diseases of the Rectum and Colon*.<sup>2</sup> An experience of some twenty years has brought the author to the not very surprising conclusion that the study of one part of the large bowel cannot be dissociated from that of the rest. He refers to the change which has come over this branch of surgery and expresses the opinion that disease of the large bowel is becoming more common and is therefore assuming greater importance. The reason is, he thinks, in the main dietetic. The highly elaborate preparation of foodstuffs has had the effect of reducing the indigestible residue to a minimum, with the result that the normal stimulus to peristalsis and digestion is diminished, especially in people of sedentary habits. In the more primitive races, whose food contains a greater proportion of undigestible cellulose, many of these ills do not arise. The author devotes a chapter to the physiology and to the bacteriology of the large intestine, and it is interesting to find here, as well as elsewhere, experimental work quoted in support of his conclusions. In discussing the vexed question of the function of the colon he says that the arguments brought forward to support the view that it is a useless and effete organ are far from convincing. One of the results of complete colectomy is to upset the fluid economy of the body. Patients who have undergone this mutilation have to take more fluid and are liable to suffer from diarrhoea after each meal. In dealing with the question of occlusion of the bowel certain experiments are quoted. The author states dogmatically that accumulation of faeces will occur in any loop, either proximal or distal to an anastomosis, and that an abscess will eventually form. The condition is not compatible with good health unless a fistula is left communicating with the excluded loop. Distension of the colon, he considers, results from fermentative processes in the faeces. The gas liberated is normally absorbed and carried away in the venous stream. Therefore to prevent meteorism either the bowel must be cleared or substances introduced into it to prevent fermentation. Post-operative ileus he holds to be due to microbic infection of the peritoneum. Proper diet and cleansing of the colon are the only means of combating it. Morphine has no specific effect.

Enteroptosis, he considers, is due mainly to weakened abdominal walls, with the consequent venous stasis due to lowered intra-abdominal pressure. For this condition he performs lateral anastomosis between the most dependent part of the transverse colon and the upper end of the

<sup>2</sup> *Diseases of the Rectum and Colon and their Surgical Treatment*. By P. Lockhart-Mummery, F.R.C.S. Eng., M.A., M.B., B.Ch. Cantab. London: Baillière, Tindall and Cox. 1923. (Demy 8vo, pp. x + 672; 215 figures, 5 plates. 25s. net.)

future. One of the chief causes of the crisis is that the Indian Medical Service has lost its attraction for young graduates of the home medical schools; the rapid Indianization of that service following the Reforms Scheme has led to uncertainty regarding the future and to the filling of the professorial chairs of the medical colleges and college hospitals, and many of the higher civil medical appointments, by Indians not belonging to the service. The provincial legislatures convey the impression that the demise of the I.M.S. would not disturb their peace of mind; one province has declared that it does not want the services of any I.M.S. officers. The disappearance of the Europeans of the I.M.S. would, the author considers, be a calamity to India.

The profession in India, Sir Patrick Hehir says, consists of three groups—the medical services of Government, independent medical practitioners, and those who practise the ancient systems. The population of India is mainly dependent for medical relief on the last two groups. Leaving out the holders of English medical degrees, and the small number of other men employed on special estates, there is in Bengal one medical graduate or qualified practitioner of the assistant surgeon class for every 2,300 persons in Calcutta, and only one for every 181,000 persons outside Calcutta. The same conditions prevail in other parts of India, although to a less pronounced degree. The practitioners of the ancient systems greatly outnumber those who practise Western medicine; many thousands practise these systems, who, whilst they do some good, also do much harm. The talents of these practitioners vary within extreme limits from being illiterate impostors and empirics, to persons versed in the ancient systems and often possessing a smattering of Western medicine. The author believes that the standard of medical education in India will fall in direct ratio to the extent to which European I.M.S. officers are removed from the teaching appointments. He holds the same view regarding the superior posts in the civil departments—the fewer held by European I.M.S. officers, the lower will be the standard of treatment in the civil population. The I.M.S. has done a great deal towards elevating the practice of medicine by Indians during the last seventy years; but to raise standards in a whole country is the work of many generations. The lower type of medical man who fails to get into other branches of the medical services in India is not likely to raise or even to maintain the standard. Sir Patrick Hehir surveys the whole field of medical education and practice in India, and states in detail the changes he considers necessary in the interests of Indians themselves.

#### WHAT THE INSURANCE SYSTEM MIGHT BE.

IN *The Old Doctor*<sup>5</sup> Dr. F. G. LAYTON has produced a novel with a purpose. With grim accuracy and subtle humour life in the "medical underworld" is portrayed as it existed in pre-war and pre-Insurance Act days, with the everlasting struggle of the conscientious practitioner to improve the seamy side of general practice alike for his patient, his colleagues, and his art.

The story is told with an intimacy of detail which is at times almost startling in its directness. To those old enough to have passed through its earlier period it will vividly recall many memories, while for the younger generation, who knew not such times, it will possess a fascination in that it contains a comparative history of their inheritance. The theme is developed mainly in dialogue, the crispness of which never falters, and centres round the personality of the "Old Doctor"—Luke Denison. The reader learns to realize what a power such men were in maintaining the honour of their calling amidst all the evils for which the old club system and the sixpenny non-visiting doctor were responsible. The ever-ready helping hand to guide the struggling Dr. Dix in his early career through the temptations to fall from the high ideals of his Hippocratic oath, which the existence of such conditions fostered, is well brought out, and the obvious outcome is seen in the welcome given to the Insurance Act by men who hailed it as the deliverance of the honest practitioner from the thralldom of hopeless inability to do the best for his patient, while

rescuing the "Back Street" poor of such Black Country towns as Winstone from the crippling anxiety about fees to meet which there never was, and never would be, any money.

The "Old Doctor" warmly welcomed the Insurance Act. "We shall be able," he exclaimed, "to see people just as often as we please without having to worry about charges," and continued, "Poor people will be able to be ill as long as they like and never a thought of a doctor's bill to frighten them." Beyond and above such present-day practical considerations were his visions of what the insurance system of the future would lead to in the ability to estimate the beginnings of ill health and so provide for the larger issues of preventive medicine.

The author is peculiarly happy in depicting the social aspect of professional life in such a town. Since Ian Maclaren's old Highland Dr. Maclure in *Beside the Bonnie Brier Bush*, there has scarcely been so masterly a portrait of the best type of general practitioner as is portrayed in Luke Denison, and were the book read widely, as it deserves to be, it would do much to dispel the misconceptions, too rife among those who have never stayed beneath a doctor's roof, as to the kind of life the average medical man leads. The realization of such a thing would go far to remove from the official mind much that now hampers the just estimation of the value of services honestly given in a persistent endeavour to push forward the whole science and art of medicine.

The author maintains a never-flagging interest, and has succeeded in making his characters "live." His literary gifts thus enable him to draw a vivid picture of all that led up to the inception and carrying through of the Insurance Act as a measure of relief from the crippling influence of club practice, and deliverance from such men as Drs. Miggs and MacFad, who will rank in fiction with the portraits drawn by Dickens and Thackeray. There can be no better summing up of the book than is provided by the last sentence, in which Luke Denison quotes from the Hippocratic oath: "Purely and holily I will keep guard over my life and my art . . . That's the scheme." To all and sundry, professional and lay, this book cannot but appeal, and it may interest readers to know that the author is generously devoting all profits to charity.

#### NOTES ON BOOKS.

THE little book on *Natural Religion*,<sup>6</sup> by Dr. JOSEPH S. BOLTON of Nottingham, is well worth reading. It lays claim to no great erudition and to no great originality. But it is written—was written, for the work is posthumous—by a man greatly in earnest, believing in his thesis, in himself, and in the value of his message. His work is so thoroughly unorthodox that it can only be criticized by a non-theologian. During the war the writer of this notice remembers a medical officer who was asked, somewhat inquisitorially, by a High Church Anglican padre, to what denomination he belonged. He replied that he was a U.C.; next day the cleric returned to the charge saying that none of his Presbyterian brethren could identify the "body." Whereupon the M.O. explained that it stood for "Unattached Christian," and the padre went his way, muttering to himself. Dr. Bolton might quite well have called his book "The Religion of an Unattached Christian," for, while his pages are full of the teaching of the Founder of our Faith, he has no use for prelates, priests, or a paid clergy of any stamp whatsoever: creeds, precedents, symbols are all thrown overboard. Natural religion is defined as the spirit of God in the soul of man, directing and controlling his conduct. "It reveals itself as an appreciation of God, strictly comparable to the appreciation of music or poetry or art." For, as a musician is a man who appreciates and enjoys music, so is "a saint a man who appreciates and enjoys God, and demonstrates God to his fellows." It is a thoughtful book written by a cultured and kindly-hearted man who had evidently great belief in his fellow men and their inherent capacity to attain to yet higher things.

**DEATHS IN THE SERVICES.**  
Captain Lionel Baker Jones, Indian Medical Service, was killed by a sniper, while working on duty, on the Loralai-Haratal road, Baluchistan, three miles from Haratal, on December 17. He was born on July 24th, 1885, the son of Dr. Samuel Jones Jones of Ryegate, Hampshire, England, and was educated at Marlborough College, Wiltshire, and at the University of London. On May 1919, he enlisted as a medical student, and was sent to the 14th Central Postal Directory, India, where he was promoted to Lieutenant on July 1st, 1917. He was discharged in 1918, and received a commission as 2nd Lieutenant, 1st Battalion, 14th Central Postal Directory, on July 1st, 1917. He was promoted to Lieutenant on July 1st, 1917.

THANKING AND REMONSTRATING

—In a letter on the above subject of 18th March 1908, Miss Margaret Hume discovered that German physicians have found that Mrs. Harriette Chivers was cured of her disease by the use of barley water. It should, however, not be forgotten that in 1808 Dr. Axel Holst of Christiania showed that barley was produced in guinea-pigs by a diet of bread and cereals, but not if raw carrot was added; on a diet of pressed potato, but not if cabbage juice was added; and on a diet of dried barley and water, but not if barley was allowed to sprout first.—I am, etc.

London, W., Oct. 22nd.

DEAR DR. VETTER.

At the present time there is a great deal of dis-

"The first thing I noticed when I stepped out of the car was the cold, crisp air. It felt like a fresh blanket after a long, hot summer. The sun was just rising, painting the sky in soft shades of orange and pink. I took a deep breath, savoring the scent of pine and the distant sound of birds chirping. It was a beautiful start to a new day, and I felt a sense of peace and tranquility that I hadn't experienced in a long time. The world around me seemed so peaceful, so serene. I was grateful for the moment, for the chance to start over and embrace the beauty of nature. It was a reminder that life is full of possibilities, and that sometimes, the best things come from the simplest of moments. I smiled, feeling a sense of hope and optimism for the future. The day ahead was full of potential, and I was ready to embrace it all. The world was my oyster, and I was determined to make the most of it. I took another deep breath, feeling the cool air fill my lungs. It was a perfect start to a perfect day, and I was grateful for every moment of it. The world was so beautiful, so full of life and color. I was lucky to be here, to experience it all. I was going to make the most of it, to live every moment to the fullest. The day ahead was full of possibilities, and I was ready to embrace it all. The world was my oyster, and I was determined to make the most of it. I took another deep breath, feeling the cool air fill my lungs. It was a perfect start to a perfect day, and I was grateful for every moment of it. was recommended for service in the Royal Air Force on August 11, 1916, and on May 26th, 1917, was decorated with the Military Cross. After being demobilized on July 25th, 1919, he resumed his medical studies and graduated M.B. and Ch.B. in Edinburgh in 1923. On January 20th, 1925, he joined the R.A.F. as captain on account of his services in the R.A.F. During the war he was captured in 1918, and was held in Germany in a prisoner of war camp until 1919. He was on leave from 1915 to 1916, and landed at Bombay the day after he joined the R.A.F. in 1915. He was on leave again in 1916, but never joined a second time.

a victory, and if wisdom and moderation are shown in the situation that will then arise, the insured population, the national health, and the credit of the profession will benefit alike.

## THE BACTERIOLOGY OF MEASLES AND SCARLET FEVER.

THE two common infectious diseases, measles and scarlet fever, the etiology of each of which has always been disputed, are now being studied by laboratory workers in Europe and America, employing all the latest refinements of bacteriological technique. These researches have thrown new light on the early stages of these infections; they have led to the formulation of some original and plausible propositions; and, though not accompanied as yet by any decisive discoveries, they have afforded fresh evidence incriminating certain organisms long under suspicion, evidence which time will test and on which experience must judicate.

The researches carried out on measles, for instance, corroborate the view that this disease owes its origin to the invasion of the body by an ultramicroscopic virus. We have received from Professor G. Caronia of Rome a paper on the etiology of measles,<sup>1</sup> in which he announces that the micro-organism he considers responsible for this disease passes through an ultramicroscopic phase in the cycle of its development, but later appears as a small diplococcus when cultivated under special anaerobic conditions on a special medium, the preparation of which has not, so far as we can ascertain, been described. He has obtained cultures of this micro-organism from the blood, bone marrow, cerebro-spinal fluid, and naso-pharyngeal secretions of children in the prodromal and eruptive phases of measles; the blood of such patients showed specific antibodies against the organism recovered in cultures. It is stated that young rabbits inoculated intravenously with large amounts of blood from measles patients developed a clinical picture resembling human measles, and the same organism was recovered from their blood. He inoculated healthy children with inactivated or attenuated cultures and conferred on them immunity to measles; he inoculated three healthy children with large and repeated doses of recent cultures, and induced a typical but attenuated form of measles, the eruption being brief but universal, and accompanied by high fever. In these patients the serological reactions were positive, and the micro-organism could be cultivated from the blood and from the filtrates of the secretions from the nose and throat.

Turning to scarlet fever, we may recall that in 1921 Dr. Mervyn Gordon, in his serological study of haemolytic streptococci, published in this JOURNAL,<sup>2</sup> stated that there are three distinct types of haemolytic streptococci which can be differentiated by agglutination tests,<sup>3</sup> and that one of them (Gordon's which never falters,<sup>4</sup> chiefly in the tonsils and fauces of "Old Doctor" Lur<sup>5</sup>). This organism, *Streptococcus* distinct from the more common club system and the *cus pyogenes*. Bliss<sup>6</sup> had found responsible. The ever-<sup>7</sup> in 100 per cent. of scarlatinal struggling Dr. Dix in his<sup>8</sup>, and noted that immune tions to fall from the high-scarlatinal streptococci agglu- which the existence of suc ent. of strains isolated from brought out, and the obvious o scarlatina cocci were not given to the Insurance Act by<sup>9</sup> red from other strepto- hopeless inability to do the bes<sup>10</sup>, 891.  
1921, 1, 632.

cocci. Tunnickliff<sup>11</sup> also isolated haemolytic streptococci from early cases of scarlet fever; these organisms were apparently peculiar to the disease in that they were specifically opsonized and agglutinated by the serum of a sheep immunized with a haemolytic streptococcus obtained from scarlet fever.

Professor G. Caronia and Dr. M. B. Sindoni<sup>12</sup> have also tackled this problem, and feel themselves justified in going a stage further than previous investigators, for they assert with conviction that this organism bears a causative relation to the disease. Their work on the serological behaviour of this streptococcus confirms that already cited, and they have also conferred passive immunity on infected rabbits by injection of serum from children convalescing from scarlet fever. They claim to have actively immunized children by vaccinating them with killed cultures, such children being afterwards exposed to scarlet fever without contracting the disease. They also inoculated five children who were convalescing from measles, and all of these children developed what is asserted to be an attenuated form of scarlet fever after inoculation with the cultures. Serological tests with these children were positive, and they were further submitted to contact with other patients with scarlet fever, but did not contract the disease.

Such heroic appeal to experiment on human beings (which, it is to be hoped, was not attended with any ill consequences) has an even more startling precedent in the case of Takahashi of Tokyo,<sup>13</sup> who injected five of his own children, aged 3 to 10 years, subcutaneously with 0.0001 c.cm. of the blood of a scarlet fever patient. No general or local reaction ensued, but a certain degree of active immunity was produced, as was shown by the fact that hypodermic injection of 0.15 c.cm. of a scarlatinal patient's blood fifty days after the inoculation, and the smearing of the child's throat with the secretion of the throat and blood of the patient fifteen days after inoculation, failed to cause any disease.

The last and most recent paper on scarlet fever to which we wish to draw attention appears in the *Journal of the American Medical Association*, and is contributed by Drs. George and Gladys Dick.<sup>14</sup> A nurse who was taking care of a patient with scarlet fever contracted the disease in a mild but typical form. Two days before the onset of symptoms she noticed that she had a sore finger, and on the second day of the disease, when the rash was intense, a few drops of pus were obtained from the lesion on the finger. A haemolytic streptococcus and diphtheroid bacillus were recovered by culture of this pus. After careful purification of the streptococcus five volunteers were inoculated by swabbing the tonsils and pharynx with four-day-old cultures of the haemolytic streptococcus, grown on sheep's blood agar slants. Three of these experiments were entirely negative, but in one volunteer the inoculation was followed by a sore throat and fever without a rash, and one developed typical mild scarlet fever. To test the possibility that some ultramicroscopic virus was also concerned in initiating the disease, sterile filtrates from the haemolytic streptococcus culture were inoculated into five volunteers, but they developed no sore throat, fever, or rash. On the eleventh day following inoculation with the filtrate four of the volunteers were inoculated with an unfiltered four-day-old culture of the haemo-

Mr. E. W. Hey Groves, F.R.C.S., professor of surgery in the University of Bristol, on Thursday, Friday, Monday, and Tuesday, November 8th, 9th, 12th, and 13th. The lectures will be given at 5.30 p.m. each day, and at the first

DRS. G. E. H. ROGER, dean of the Paris Faculty of Medicine, and L. FAURE, professor of surgery in the same faculty, L. HUGONOT, honorary dean of the Lyons Faculty of Medicine, and J. LAURIE de FLAURY, member of the Academy of Medicine.

## THE UNIT SYSTEM.

SOME considerations which have led to the abandonment of the unit system for surgery at the London Hospital are set forth in a letter from Mr. H. S. Souttar published in this issue (p. 783). Mr. Souttar has been director of this unit since it was originally organized in 1920. In his letter he explains that "the fundamental principle was that certain men, who had attained some distinction in their profession, were to be selected, invited to withdraw from private practice, and by the payment of a salary enabled to devote the whole of their time to teaching and research." The aim was admirable, but Mr. Souttar's experiences suggest that the plan does not yield the desired results. He points out at least three defects in the system which seem to warrant further inquiry. He deals first with the effect upon the teacher of being withdrawn entirely from private practice. He fears that it narrows his horizon to viewing both the disease and patient from the standpoint of the hospital ward only. Secondly, he regards the advantage to the student as relatively small, although the main disadvantage which he has himself observed is that when the student goes into practice he cannot have the benefit of the chief of the unit as a consultant for his private patients. Thirdly, Mr. Souttar, during his three years' experience, discovered that a director's opportunities for research were restricted by the absence of suitable cases to furnish material for clinical study, as doctors are apt to send their hospital patients into the wards of those members of the hospital staff they can call into consultation on their other and non-hospital patients. The account Mr. Souttar recently gave of the surgical clinics of Switzerland (*BRITISH MEDICAL JOURNAL*, June 2nd, 1923) shows that he is not blind to the merits of the Continental system nor unready to acknowledge shortcomings in our own. But it is evident that he thinks that the unit system as it has been essayed in this country is not likely to introduce the best features of Continental methods whilst preserving what is good in our own. The adequacy of our present hospital system to perform its threefold function of treatment, education, and research has been for some time the subject of serious discussion. In 1920 the plan was adopted of organizing at selected hospitals "units" with the object of improving at least the education and research sides. The plan was admittedly experimental, and it is not wise to ask too soon for results as though the experiment had been carried to its conclusion. Nevertheless, when the London Hospital finds grounds for modifying the arrangement, and Mr. Souttar describes the system as not generally suitable for our requirements, at least in the province of surgery, it may be time to pause and ask whether inquiry should not now be made into the working of this and other plans that have been introduced in the last few years.

## THE HARVEIAN CELEBRATION.

THE memory of Harvey, its greatest Fellow, was celebrated, as is customary, at the Royal College of Physicians of London on St. Luke's Day. In the afternoon Professor E. H. Starling, F.R.S., delivered the striking oration published last week, and in the evening the Fellows dined together in the College. At the meeting in the afternoon the Baly medal was presented to Mr. Joseph Barcroft, C.B.E., F.R.S., reader in physiology in the University of Cambridge, and the Bisset Hawkins medal to Dr. T. M. Legge, C.B.E., Medical Inspector of Factories, Home Office. The Baly medal was founded by Dr. F. D. Dyster in 1886, in memory of Dr. William Baly, physician to St. Bartholomew's Hospital, who was killed in a railway accident in 1861. The trust directs that the medal shall be presented every alternate year to the person who has

most distinguished himself in the science of physiology, especially during the two years immediately preceding the award, and is not restricted to British subjects. The Bisset Hawkins medal was founded in honour of a Fellow of the College who did valuable pioneer work in respect to medical statistics. It is awarded every third year to a medical practitioner (British subject) whose work in advancing sanitary science or in promoting public health is considered deserving of special recognition. The dinner is held in accordance with Harvey's deed of gift made in June, 1656, just a year before his death. The gift, which consisted of his patrimonial estate at Burmarsh, in Kent, was to be used to promote friendship between the members of the College, and Harvey directed that "once every year there shall be a general Feast kept within the College for all the said Fellows that shall be pleased to come," and that on that day an oration should be delivered exhorting the members of the College "to search and study out the secrets of Nature by way of experiment." This year the toast of the Harveian Orator was given by the senior censor, Dr. Fawcett, and suitably acknowledged by Professor Starling. The College had the pleasure of welcoming Sir Robert Philip, President of the sister College in Edinburgh, and also Sir John Bland-Sutton, President of the Royal College of Surgeons of England; among the other guests were Lord Chelmsford, chairman of the council of University College, the Minister of Health, Lord Justice Atkin, Professor Langley of Cambridge, the heads of the Medical Services of the Navy and the Air Force, Sir Squire Sprigge, and Dr. R. W. Innes Smith of Sheffield, who, as has already been reported, recently presented a portrait of Sir Charles Scarburgh to the College; it was on view in the large library, and excited much interest. It was in the collection at Temple Newsam or Newsome, the famous old house near Leeds which, with its park and farm, was acquired some time ago by the corporation and was formally opened to the public last week. The place once belonged to the Knights Templars. It was afterwards the home of that learn'd and fair and good Mary, Sidney's sister Pembroke's mother. Darnley, the husband of Mary Queen of Scots and father of James VI of Scotland, was born there. Soon after James VI became James I of Great Britain the place passed into the possession of Sir Arthur Ingram, in whose family it remained until the end of the eighteenth century. The house contained many portraits, and those of Strafford, of the mother of Darnley (Countess of Lennox), of Darnley himself, of Mary Queen of Scots, and of their son, remain there. How Scarburgh's portrait came to be in the collection does not seem to be known. When it was sold not so long ago it was described as the portrait of a navigator, probably because some mathematical instruments were on the table beside the sitter. Scarburgh was in fact a mathematician, and lectured at Cambridge on the subject. He was ejected from his fellowship at Cambridge during the Caroline revolution, and entered at Merton College, Oxford, where his friendship with Harvey, which continued until Harvey's death, began. He settled in London in 1648, and two years later was admitted a Fellow of the Royal College of Physicians. Scarburgh's name is also connected with the history of the Royal College of Physicians of Edinburgh. He was physician to Charles II, and also to the Duke of York, afterwards James II; he went with the Duke to Edinburgh, where the party stayed at Holyrood and Englishmen first played golf, being initiated on the Leith links. The story is that Scarburgh's interest was obtained by Pitcairn, Sibbald, and some other physicians in Edinburgh, and that through the Duke of York he obtained from the King the grant of a charter for the Edinburgh College. Scarburgh was anatomical reader to the Barber-Surgeons' Company, which had his portrait painted in 1650; that portrait still hangs in the Barber-

by the Gas Cylinders Committee. Nearly the whole of the present report is concerned with this problem; its first part contains a general description of the vacuum vessel and a discussion of the theory underlying its use for the storage of very cold liquids. A detailed account of the methods of manufacture of vacuum vessels is given in the second part, and in the third and fourth some important aspects of the use of vacuum vessels are discussed. The Oxygen Research Committee had the advantage of starting with a knowledge of the late Sir James Dewar's pioneer researches into the liquefaction of gases; to him was due not only the invention of the double-walled metal vacuum vessel, but also the discovery of the highly adsorbent properties of charcoal and other materials at low temperatures. His application of this to the construction of metal vacuum vessels was the determining factor in rendering possible the use on a large scale of liquid oxygen and liquid air. The Oxygen Research Committee was concerned to make possible the increased use of oxygen in the liquid form, and had first to consider the difficulties of economic production on a commercial scale and those of handling and utilizing the liquefied gases. This was the immediate need, for, except in the most favourable circumstances, the methods then available did not render practicable the use of liquid in place of gaseous oxygen, though the latter method was severely handicapped by the weight of the containers. The Committee, therefore, has been principally concerned with the development and further use of the double-walled metal vacuum vessel to contain liquid oxygen. As has been said, the major part of the report is devoted to this matter, and practical conclusions are drawn for the benefit of manufacturers. The report does not deal with certain other problems the Committee has considered; among these is the development of vaporizer devices for the administration of gaseous oxygen from a liquid supply. Advances have been made and further improvements are constantly being introduced, and about these the Committee intends to issue another report. It is pointed out that a matter which has been and remains one of considerable concern, especially to the medical profession, is the price of oxygen. The Committee is not yet in a position to express an opinion on the possibility of a reduction in the present cost of oxygen, but it is convinced that, for medical purposes especially, it is a matter of vital importance, since the current prices restrict its use for such purposes to quantities much below those in which it could usefully be employed. The purity of the gas is also a matter of great consequence when it is required for administration to patients.

#### THE GUILD OF ST. LUKE.

THE annual service of the Guild of St. Luke, the Evangelist and Physician, was held on Thursday evening, October 18th, St. Luke's Day, in St. Paul's Cathedral. Members of the guild and their friends attended in good numbers; many of the medical practitioners and students who were present wore academic dress, and joined in the solemn procession which took place at the end of the service. The organist and choir of St. Mary Abbott's, Kensington, gave valuable help, and evensong, which was fully choral, included the anthem "Save us, O Lord" by Bairdon. The lessons were read by the warden, the Rev. J. Basil Rust, and the guild honorary secretary, the Rev. H. Kirkland-Whittaker, M.D. One of the four hymns sung during the service, "Thou to Whom the sick and dying," was rendered to the tune "Vervey," specially composed by Dr. Kirkland-Whittaker, this being the third occasion of its use at a guild annual service. The preacher was the Rev. Canon Simpson, D.D., who gave a striking address on the place of the work of the medical profession in the larger purposes of God. He called attention to the sympathy and faithful-

ness which characterized the friendship of St. Luke for St. Paul, and then proceeded to show how St. Luke had absorbed and recorded the cardinal principle of St. Paul's teaching—namely, reconciliation—the reconciling to God of all things both in heaven and earth; not as being the ambulance work of a disappointed deity; but rather as the final stage of a great universal spiritual process. Thus it was that St. Luke's gospel, with its deep appreciation of the essential characteristics of human nature, and its many parables of an understanding and a healing God, became indeed the gospel of the "Gloria in excelsis," the gospel of the rejoicing spirit of God its Saviour. In all her various manifestations Nature, whether human or physical, displayed both beauty and ugliness, joy and terror, but there was nevertheless nothing uncoverable by the great conception of God the Saviour. Christ had recognized the healing art as being part and parcel of His own work of reconciliation. The offertory, after defraying the cost of the service, was devoted to the mission fund of the guild. In the final procession the banners that were carried, the vestments of the clergy, and the robes of the graduates made up an impressive picture which brought a noble service to a fitting termination.

#### THE LISTER WARD AT GLASGOW.

MR. JAMES A. MORRIS, who is a distinguished Scottish architect, has published "a humble plea for the retention" of this famous ward in the Glasgow Royal Infirmary, written from a layman's point of view. We welcome this well reasoned and clearly stated contribution to a somewhat unfortunate controversy, and would venture to express the hope that Mr. Morris's plea may receive the full consideration it deserves. He gives us good grounds for his contention that this ward may be preserved as Lister knew it, without any prejudice to the present or any future scheme of enlargement or reconstruction, and shows how it might be made part of the gate-house block. All the world is united in admiration of Lister and his work, and may claim to be allowed a voice in deciding the fate of the ward. Glasgow people and their infirmary governors should surely admit this claim, and allow due weight to the sentiments which have so strong a hold on us all. It may well be worth while to preserve the old ward, not only out of affectionate respect for Lister, but also as an object lesson to future generations, from the inspection of which they may judge of the enormous improvements which have taken place, and yet may realize that the palatial modern operation theatre and surgical wards would be of little avail in themselves but for the discoveries which were applied to surgical practice in this shabby old building. Funds are being raised and generous contributions made to restore and preserve the ship in which a great English sailor lived and gloriously died. Must it be said by future annalists that at the time when this proper tribute was being paid to patriotic sentiment, the Scottish people turned a deaf ear to the prayer for the preservation of the building where another great Englishman began that epoch-making work which benefited and still continues to benefit the whole human race?

#### THE SOCIETY OF MEDICAL OFFICERS OF HEALTH.

THE annual meeting of the Society of Medical Officers of Health was held on October 19th at the house of the society in Upper Montague Street, when the President, Dr. Naylor Barlow, M.O.H. Wallasey, delivered an address. In the course of it he observed that, of the new activities of the public health service, that dealing with maternity and child welfare was producing the best results. Under the new conditions many children who survived infancy would be classed as healthy who would previously have been reckoned weaklings. Many of the disabilities of adult life

A. ABRAHAM (*Dent. med. Woch.*, August 31st, 1923, p. 1156) confirms the observation made by Hirsch in 1920 that a 5 per cent. solution of cocaine is quite as effective in

The author recommends the following prescription :

|                                    |     |     |     |
|------------------------------------|-----|-----|-----|
| Cocaine, hydrochlor.               | ... | ... | ... |
| Supramin, hydrochlor. (1 in 1,000) | ... | ... | ... |
| Sol. pot. sulph. (2 per cent.)     | ... | ... | ... |
| Sol. acid. carbol. (0.5 per cent.) | ... | ... | ... |
|                                    | 25  | 50  | 100 |

at the Bar and nose department of the university hospital in Cologne the author has found this preparation not merely as satisfactory anæsthesia as a 20 per cent. solution of cocaine; there is the additional and great advantage of reduced cost and risk of cocaine poisoning. This weak solution can be relied on even for endotracheal operations.

Laryngology and Otology.

305. Diagnosis and Treatment of Septic Sinus Thrombosis

REGARDING the operation which should be performed on the jugular vein in septic sinus thrombosis, KENDEL, C. PHILLIPS (*Journ. Amer. Med. Assoc.*, August 25th, 1923, p. 633) says that opinions still vary. The majority of

 ပုဂ္ဂိုလ်တို့သည် အသက် ၁၈ နှစ်အထက်ရှိသူများသာ ဖြစ်သည်။

to ligate above the entrance of the facial vein, but practically the lower ligation is fully as effective and is much more easily accomplished. A complete dissection of the vein is still advocated by some operators on the ground that it is

investigation, particularly when made in the lower portion of the

the already weakened and exhausted patient to prolonging anaesthesia, counts much in its favour, and Nature seems to care for all the rest, except in occasional cases in which the

prolonged temperature is finally relieved by opening up the bulb region freely from the mastoid wound. The lower neck operation can be completed in from ten to twenty minutes. The bulb region is anastomosis the only area in which real

tion. If the ligation method is followed, the ligatures should be applied to the vein sufficiently far apart to enable the

operator to sever the vein. It has been Rhipps's experience that in ligation cases the neck wound heals more promptly and with less deformity than when the vein is resected.

### Intratracheal Injections of Antitoxin in

ΕΛΛΗΝΙΚΗ ΔΗΜΟΚΡΑΤΙΑ

J. GHROU (*loc. cit.*, p. 709) states that Remon and Mignot used the tracheal route for injection of antipneumococcal serum in the treatment of indigenous pneumonia and for antistreptococcal serum

in pulmonary tuberculosis when the sputum contained streptococci, while Katcher and Bordet in a case of pulmonary gangrene gave an intracacheal injection of anti-*Streptococcus antiphilii* and antistreptococcal serum. Clifton

now reports three cases of very severe layngeal diphteria in children, aged 4 years, 16 months, and 9 years, in whom diphteria antitoxin was injected through the tracheotomy well as by the ordinary method, and all recovered.

recovered. This method has never been used before in the treatment of diptheria, although Renon and Mignot treated a case of haemophilus by intracerebral injections of diptheria

antitoxin. The treatment consists in injecting 2 c.cm. hourly for the first day, and if there be an improvement next day for I.c.cm. every two hours. To avoid a violent cough the injection is given very slowly, ten minutes being taken for

the injection of 2 c.cm. of warmed serum, which is given with a Luer's syringe through the tracheotomy tube.

J. B. GREENE (Boston Med. and Surg. Journ., August 9th, 1923, p. 200), advocates utilizing the thromboplastic action of the tissues in the prevention of haemorrhage in tonsillectomy.

The following table shows the results of the regression analysis. The dependent variable is the percentage of respondents who answered "yes" to the question "Do you think that the government should do more to help the poor?" The independent variables are the demographic and attitudinal variables listed in the table. The results show that the demographic variables explain a small portion of the variance in the dependent variable, while the attitudinal variables explain a larger portion. The overall model explains 12% of the variance in the dependent variable.

be met with when the upper third of the tonsil is being dissected out the tonsil is immediately replaced and held firmly in situ until haemorrhage has ceased, after which

The remainder is removed by slow action of the wire snare. Finally, after complete severance, the tonsil, suggests the author, should be held firmly and accurately in its position for two minutes, thus allowing sufficient time to clasp the tissue over the bleeding vessels by a firm clip. By the time the vessel is closed the patient is usually unconscious, possibly owing to the action of the ether vapor. The patient is then placed on his back and the head is supported by the hands of the assistants. The patient is then placed on his back and the head is supported by the hands of the assistants. The patient is then placed on his back and the head is supported by the hands of the assistants.

to neutralize the toxins produced by the fertilized ovum, which have penetrated into the system owing to hepatic insufficiency.

## Roll of Honour.

## MEMORIAL TO MEMBERS OF THE NEW SOUTH WALES BRANCH WHO DIED IN THE WAR.

ERECTED BY THE MEMBERS OF THE BRANCH.

SOME time ago we published an account of the unveiling in Westminster Abbey of the tablet to the memory of those members of the R.A.M.C. who gave their lives in the war, and illustrated the article with a photographic reproduction of the memorial tablet. We have since had occasion to describe the unveiling of several other similar memorials, and it is not too late to reproduce a photograph of the tablet erected by the New South Wales Branch of the British Medical Association to those of its members who died on service. The memorial, a photograph of which is reproduced above, is of bronze mounted on marble, and has been erected in the hall of the British Medical Association building, Sydney; it was unveiled on December 6th, 1921, by Dr. Fourness Barrington, then President of the Branch, who delivered the following eulogium:

Let us remember with all humility and gratitude, before God and man, those brave colleagues of ours in the Medical Profession of New South Wales, who, in serving their Country in the Great Five Years' War of 1914 to 1919, gave their lives for the freedom of the world.

Their names are perpetuated in the Roll of Honour embossed on this beautiful tablet of bronze erected to their memory, for the unveiling and consecration of which we are to-day assembled.

At the call of their King and Country they left all that was dear to them, endured hardship, faced danger, and finally passed out of the sight of man by the path of duty: most of them resplendent with youth, full of vigour, and overflowing with hope and happiness.

We tender them our homage: and offer them our tribute of reverence and of thankfulness for all that their self-sacrifice helped to achieve.

By their loss we are the poorer: in their noble example we are the richer.

Let us keep their example before us in sad but proud remembrance. Let it be a light to inspire and guide us and those that come after us in the service of humanity.

*"Their Glory shall not be blotted out . . . and their name liveth to all generations."*

GOD SAVE OUR KING!

British Medical Association.

PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, 1923.

SECTION OF SURGERY.

Sir Henry M. W. Gair, K.B.E., C.B., C.M.G., F.R.C.S. (Edin.), President.

DISCUSSION ON

ANÆSTHETICS FROM THE SURGEON'S POINT

OF VIEW.

OPENING PAPERS.

I.—WILFRED THOTTER, M.S., F.R.C.S., Surgeon, University College Hospital, London.

The Relations of Anaesthetist and Surgeon.

A surgical operation, like every other product of concerted action, demands for its complete success something more than the mere exercise of the special aptitudes and knowledge of those who take part in it. It demands from each actor not only the full exercise of his own craft and an absorbed attention to its peculiar problems, but also a sympathetic awareness of the problems before his fellow actors, and a willingness to regard their difficulties as in some degree his own.

This sympathetic understanding of one another's work is indispensable between the surgeon and the anaesthetist if the full advantages of modern surgery are to be available for the patient. Surgery has now reached a stage in which the narrowness, but in which success is to be looked for with confidence if every possible precaution is taken and every avoidable risk is met. In such circumstances there must be the closest understanding between anaesthetist and surgeon in the choice and modification of methods, and in deciding where one or other can yield a point or must resist any compromise of its requirements. The successful management of anaesthesia in what we may call these frontier provinces of surgery demands so full a knowledge of the actual surgical conditions that one is inclined to suppose that there will be in the future a closer and closer approximation of the training of the anaesthetist to that of the surgeon, and a more and more complete assimilation of the anaesthetist into the surgical team. This consideration is to my mind much reinforced by the fact that so many of the most valuable methods of inducing anaesthesia are such as the various regional and infiltration methods—these are definite surgical procedures in themselves and seem to make it obvious and inevitable that the anaesthetist should take his part in the ensuing operation.

In certain operations such as those on the mouth, the nose, the pharynx, and the upper air passages, the relations of anaesthetist and surgeon have always tended to be rather confused and difficult to regulate. Here again it seems probable that the solution of difficulties will ultimately be found in the anaesthetist joining the definitely surgical group of participants and taking his part with sterile apparatus and hands in the operation itself.

In making these suggestions my object is less advocacy than a suggestion. I think such an evolution of the status of the anaesthetist is on the whole to be desired, I put it forward here merely as a probable development, without in any way wishing to carry conviction that it should be actively sought after.

The Anaesthetic Procedures now Available.

At a time when the prestige of operative technique is so unanimously and so deservedly high, it may be not without point to remind ourselves that, however much we may admire and emulate the workmanship, this is not and cannot be the ultimate aim of the surgeon. Beautiful workmanship in his patient is as safely, as promptly, and with as little disturbance of mind and body as his skill and judgement allow him to do. Surgery, then, as an art is, and must always be, reservedly and humbly practical, and such artistic beauty as it can possess must come not more from the craftsman's hand

than from courage, judgement, patience, and a willing submission to working under difficulty and restraint. Such reflections are not without relevance to the subject of anaesthesia from the surgeon's point of view. In judging the value of a given method he will, of course, insist upon being given a reasonably quiet field for his work, but will ask no more than is adequate for effective workmanship and will be prepared to submit to any restriction, however irksome, or any justifiable modification of his method that can be shown to be on the whole to the patient's advantage.

When we turn to the various means of producing anaesthesia, it is at once clear that in spite of the great progress that has been made of recent years there is no single method capable of general application to all cases. Indeed, one may say that the present time is more than ever the fact that in every individual case the choice of an anaesthetic must be made from a large number of possibilities, and that this choice frequently involves very careful consideration.

In going through the list of the various methods I shall limit myself strictly to matters within my own experience, and would be understood as claiming no greater validity for the opinions I shall express than is due to impressions acquired in clinical work. It will be convenient to enumerate the methods I am familiar with and to make on each in turn what comments seem necessary to the purpose of this paper. We may classify the methods to which I shall refer in the following simple way:

1. Inhalation Methods.—Ether; chloroform; nitrous oxide.
2. Regional Methods.—Spinal; sacral; nerve trunk anaesthesia.
3. Local Methods.—Infiltration.

*Inhalation Methods.*

Ether is the nearest approach we possess to an anaesthetic of general use, and if one were limited to a single form of anaesthesia the inhalation of ether would undoubtedly have to be chosen. With all the advantages of modern methods in preparing and using the drug, it has many serious drawbacks. It is not merely as a means of rendering unconscious that it is valuable, but with a broad view of the patient's interests. Either anaesthesia renders possible the local and limited interference of the surgeon only by producing a state of coma that is uncomfortable and disgusting to enter druging the whole body of the patient and putting him into a state of coma that is uncomfortable and disgusting to enter even more disgusting to recover from. The stimulating effect of the drug is such as to overdrive the circulatory and respiratory activities of the patient throughout the administration, and thus to add seriously to the exhausting effect of the operation. It is not seriously irritating to the respiratory organs and the stomach, and thus frequently leads to coughing, and usually to vomiting, in the immediately post-operative period. There can be no doubt that the most absolute exposure is of great value for at least the first twenty-four hours after all serious operations, and that a liability to cause post-operative vomiting should properly be regarded as a grave disadvantage in any anaesthetic method.

The advantages of ether as a case of administration, immediate safety, and profoundity of anaesthesia. It is seen at its best in operations of moderate length and severity, when it can safely be preceded by narcotic drugs, and in operations where the wound will not cause vomiting to be painful. In very severe and long operations that are apt to be followed by respiratory to be shallow, or coughing ineffective. In very severe and long operations that are apt to be followed by respiratory to be shallow, or coughing ineffective. In very severe and long operations that are apt to be followed by respiratory to be shallow, or coughing ineffective.

*Chloroform* is probably at the present time less used and less estimation as an anaesthetic than it has ever been. Speaking with all proper diffidence, I do not hesitate to say that in its own proper field—a matter for the most careful consideration—it still has uses for which no effective substitute has been found, and that it remains an indispensable ally to the surgeon.

The numerous disadvantages of chloroform included its immediate danger, the relative lack of depth in the anaesthesia it produces, its not incommensurable irritant effects on its respiratory and gastric mucous membranes, and, above all, its capacity to produce the so-called delayed chloroform poisoning.

Over against these must be set its power to produce in suitable cases a smooth and placid anaesthesia unclouded by the artificial and exhausting floridity of the ether patient.

being  
acting  
ally

between the pictures of Marx and Darwin claims science as a weapon in the fight for emancipation by the proletariat. The day of the persecution of scientists has gone.

Russia works slowly but she gets things done. Probably for years to come there will exist conditions in that country which will be disturbing to sanitarians accustomed to the ordered security of English life. But the definite and sustained effort to spread scientific knowledge will produce in that country, which is almost a continent, changes of the greatest world importance. And not least significant of present movements in Russia is the expressed desire for a close and cordial entente with scientists and medical men of all other countries.

## England and Wales.

### THE WELSH NATIONAL MEDICAL SCHOOL.

EARLY this year we reported that the University College of South Wales and Monmouthshire was seeking a new charter, and that the Privy Council had criticized the draft and expressed the view that it would be best to constitute the Welsh National School of Medicine as a separate constituent college of the University of Wales, to be governed, under the University, by a council and senate of its own, as recommended in the report of the Royal Commission on University Education in Wales. It was later pointed out by the Privy Council that the principal objects of any scheme should be to provide an organization which would afford the school the best opportunity of developing successfully into a first-rate centre of medical teaching and research, give it a genuinely national status, and at the same time recognize the special interests of the Cardiff University College in it. The annual report of the Council of the College, presented to the Court of Governors at its last meeting, in referring to the charter, stated that a large and representative committee which had been appointed to consider the objections of the Privy Council hoped to report in due course. Reference was also made in this connexion to the communication received from the Secretary of the Conjoint Board in England, stating that the school was recognized provisionally for the complete curriculum, for one year, from October 21st, 1922, and indicating certain conditions which should be fulfilled if the recognition was to be permanent. Subsequently a communication was received from the Senate of the University of London stating that subject to compliance with similar conditions the Senate would be prepared to recognize the school as an institution from which the University would receive certificates for the complete course of medical education preparatory to the M.B. and B.S. examinations. The conditions, the report continued, related mainly to the provision of additional beds for the medical unit and the appointment of additional teachers. The authorities of the Cardiff Royal Infirmary professed themselves unable, in view of existing financial circumstances, to provide any additional accommodation, but the difficulty has been overcome by a reallocation of the beds in the hospital, which will provide the necessary number for the medical unit. With the approval of the University of Wales, arrangements have been made by which members of the staff of the Cardiff Royal Infirmary will become recognized clinical teachers in the medical school and receive honoraria for their services. A total sum of £500 a year has been provided in the budget for the coming year as a contingent sum for this purpose. An appeal has been made for a sum of £5,000 a year to comply with the conditions attached to the grant of a like amount made by the University Grants Committee. The sum required, it is stated, is practically assured and will be provided mainly by contributions from local authorities from the proceeds of a rate of one-eighth of a penny. To meet the additional expenditure of the school for the past academic year a sum of £2,169 has been transferred by the Appeal Fund to the College; a sum of £18,363 is still required to meet the deficit for the year. The University Council has decided that its grant to the medical school shall be fixed at £14,575 a year for a period of three years. The total income of the school for the last

academic year was thus £16,744, but the whole amount has not been expended, and the surplus of £855 has been reserved for the purchase of necessary equipment. The interesting announcement is made that it is proposed to establish a lectureship in orthopaedics in the Welsh National Medical School; it is hoped that for this purpose a contribution may be made by the trustees of the Welsh Hospital Netley Fund, which may be utilized for a purpose having relation to the disabilities of ex-service men. Probably no more suitable destination for the funds in hand could be found than the endowment of the lectureship proposed. A couple of years ago the College made an appeal for a capital sum of a quarter of a million, and we learn from a report of the meeting of the Court of Governors in the *Western Mail* that towards this amount a sum of £80,000 has so far been subscribed.

### LIVERPOOL MEDICAL INSTITUTION.

At the first meeting of the eighty-fifth session of the Liverpool Medical Institution, held on October 18th, the President, Dr. J. Hill Abram, delivered an inaugural address, taking as his subject "Looking Back." Members and associates were received by the President prior to the delivery of his address. The President limited his retrospect to forty years, dating back to the year he became a medical student. He first touched upon the progress that surgery had made, alluding to the evolution of antiseptic surgery and aseptic methods, pointing out that the great war had brought into prominence the importance of the antiseptic method in wound treatment. He thought that the value of speed in operation, which in the pre-anæsthetic period was considered of great importance, should not be overlooked. He considered that the greatest advance had been made in orthopaedics, and critically observed that the great object of medicine was to prevent resort to surgery. Out of the science of bacteriology born some forty years ago sprang vaccine and antitoxin therapy. As was often the case in the history of medicine, the anticipation connected with new remedies fell short of realization. It was in that class of case where failure was signal that our knowledge was wanting, in other words the elaboration of antibodies was still an unknown factor in such cases, and as an example he cited the failure of vaccine treatment in coryza. On the other hand, he had evidence of the striking effect of vaccine treatment in the early stage of croupous pneumonia. After a tribute to the great service the discovery of x rays by Roentgen had rendered to medicine, he passed on to consider the relation of the endocrinal glands to body metabolism. The efficiency of thyroid treatment in myxoedema was frankly admitted, but the treatment of Addison's disease by adrenaline and tuberculin had been distinctly disappointing. In alluding to the elaboration of clinical methods of investigation of disease by expensive instruments, Dr. Abram drew attention to the obvious fact that such methods could only be carried out in hospitals. There was a tendency for the student to think more of these methods and overlook the cultivation of sight, hearing, and touch in diagnosis. The trained senses after all were those factors on which the majority of practitioners would have to rely in the treatment of disease, especially in districts remote from towns. In conclusion he deprecated the tendency to publish jejune observations disguised as a preliminary note, and urged the importance of cultivating lucidity, a word to which the late Matthew Arnold, in an address delivered in 1882 at the opening of the Royal Infirmary School of Medicine in Liverpool, gave the meaning "the ability to see things as they are." The temptation should be resisted to publish, at the instance of a clamorous press, matters in which research was still necessary and authoritative statements quite out of place. The address was critical throughout, and was much appreciated by the members. Dr. Hope, M.O.H. Liverpool, proposed, and Dr. Henry Harvey seconded, a vote of thanks, which was carried unanimously with acclamation. Afterwards the President entertained the members to refreshments followed by a concert of Elizabethan music, and the audience was delighted by madrigal and song, taken alternately from music of the sixteenth century. Mr. Walter E. Bridson, F.R.C.O., proved himself to be an efficient accompanist of the songs, which were rendered with great taste.

elected president of the Royal College of Physicians in 1790, in the hall of which college his portrait by Raeburn is to be seen. As a young man he attended to the poet, Robert Fergusson, when the latter suffered from an attack of acute mania, and was placed in the City Bedlam, a horrible institution, which stood on the site now occupied by the Royal College of Physicians Laboratory. After passing through the attack of mania Fergusson fell into a melancholia and ultimately died of exhaustion, on October 16th, 1774, exactly 149 years ago. Dr. Andrew Duncan was so overcome with the dreadful surroundings in which Fergusson, a man of sensitive feeling, was treated, that he determined to provide a suitable mental hospital for Edinburgh to take the place of the City Bedlam. Years went by, however, and Dr. Andrew Duncan apparently forgot his good intentions. He was a very busy man and Lord Cockburn says of him that he was a member of more societies of every kind and was actually the chairman or president of more societies than any other man in Europe. He is entitled to the credit of having founded three Royal corporations—no mean feat for one man.

An event which happened in the winter of 1786-87 brought back forgotten memories to the mind of Duncan; this was the visit of the poet Robert Burns to Edinburgh, who on arriving in Edinburgh at once set out to find the spot where the poet Fergusson—to whom he was indebted for some of his inspiration—was buried; with an honesty and generosity which were remarkable he erected a tombstone to his memory, on which he records his own gratitude. Andrew Duncan was interested in Burns and subscribed to the Edinburgh edition of his poems, and no doubt this action by Burns made a deep impression upon him, seeing that Fergusson had been his patient. Three years afterwards when he was elected president of the Royal College of Physicians, the first thing he did on the day after his election was to visit the cell in the City Bedlam in which Fergusson had died. He then called a meeting of the Council of the College and proposed that they should consider the question of erecting a mental hospital for Edinburgh. A committee was appointed and a scheme for the erection of such a hospital was launched under the auspices of the Lord Provost in 1792; towards it the College voted a sum of twenty-five guineas. Thus the first action the College took in this matter preceded the reforms instituted by Pinel in Paris by two years, and the scheme itself was publicly announced six days before the proposal to erect a retired habitation or Retreat for the Society of Friends. Owing to the Napoleonic wars the times were troublous and money was scarce, and as the hospital was designed on a fairly large scale it was not opened till 1813.

The College did something more than initiate the steps by which the Royal Hospital at Morningside was founded, for in 1853 it approached the managers of the hospital and requested them to give permission to Dr. David Skae, the then physician superintendent, to lecture on mental disease and to make use of the clinical cases at Morningside. This request was immediately granted, and four days afterwards Dr. Skae delivered his inaugural address. The managers of the Royal Hospital at Morningside, under the guidance of Dr. Andrew Duncan, entertained the highest ideals of treatment, and they have continued to be an exceedingly enterprising and progressive body. First, they built the old East House and introduced the methods adopted at the Retreat at York, which, though proposed later, had been opened before the East House. They then built the West House for the poorer classes of patients, and lastly, exactly a century after the launching of the original scheme, Craig House was opened, an institution largely due to the inspired vision and foresight of Sir Thomas Clouston. It was, Professor Robertson said, perhaps the most beautiful building in Edinburgh from an architectural point of view, and occupied the most picturesque site in the city. The courage of the members of the Board, who planned such an institution, was striking. At the present day people seemed afraid to launch out into new enterprises, while thirty-five years ago the managers of the Royal Hospital at Morningside incurred a debt of nearly £150,000 to build a mental hospital worthy of the metropolis of Scotland and of the University of Edinburgh. The various institutions now controlled by the managers, if they were to be built at the present time in the same style, would cost nearly half a million pounds. Four years after they had willingly granted permission to the superintendent to deliver lectures on mental disease they gave a sum of £10,000 to the University to endow a chair of psychiatry.

The first special course of lectures on mental disease was delivered by Esquirol of Paris, and within the first three or four years at least three eminent Scotsmen attended Esquirol's lectures. One of these was Andrew Combe, who left money which helped to found the readership in psychology in Edinburgh University; another was Sir Robert Christison, who attended the lectures in 1821 and in the following year incorporated part of the information gained in his lectures on

medical jurisprudence. Sir Alexander Morison attended the lectures in 1818 and was so impressed that five years afterwards he made a strong endeavour to get a lectureship or professorship on this subject instituted in Edinburgh. One of his proposals was that the visiting physicians at Morningside should deliver the lectures. The second proposal came from the principal of the University, Dr. Baird, who suggested that the College of Physicians should undertake to provide a lecturer. This request was not so surprising as it now seems, because at that date the duty of providing medical attendance to the patients at Morningside was gratuitously performed by certain Fellows of the College. Professor Alison, in giving evidence before a Royal Commission in 1826, suggested that there should be a professorship. None of these proposals were carried out at that time, although since then they have all come to pass. Having failed in his efforts to get any of his ideas adopted, Sir Alexander Morison delivered a course of lectures in Edinburgh in 1823, and he or his son subsequently lectured annually for the next thirty years. In 1853 he retired, but, as has been pointed out, when his lectures were about to cease the College of Physicians induced the managers at Morningside to allow Dr. Skae to lecture; subsequently, when Dr. Skae died, Dr. Clouston carried on the lectureship, and, as we all know, lectured most brilliantly and successfully.

Sir Thomas Clouston lectured for three or four years in association with Professor Laycock, who took a very keen interest in mental disease and regarded it as the most important special branch of medicine. Professor Laycock was succeeded by Professor Grainger Stewart, another great teacher. He, however, did not take the same interest in this special subject, nor did he possess the same knowledge of it as Laycock. Sir Thomas Clouston was then appointed University lecturer on mental disease. It is interesting to know that this lectureship was the first to be created in Edinburgh University, or perhaps in any Scottish university. There are now over 170 lecturers attached to Edinburgh University alone.

The authorities of Edinburgh University showed that their sympathy and interest in the teaching of this subject was not diminished when negotiations took place for the creation of a chair of psychiatry, and the University has the honour of being the first of the older universities to establish such a chair.

It would appear to be the fact, that the Edinburgh School of Medicine is the only school in the world in which special lectures on this subject have been continuously given for 160 years, and they trace their descent directly from Esquirol. After his retirement and death the lectures in Paris seemed to have lapsed; in London, about the middle of last century, they became somewhat irregular; the Germans did not begin to give special lectures on this subject till a later period. The Edinburgh School of Medicine therefore occupies an important and very honourable position in the history of this subject, and for this we are largely indebted to Sir Alexander Morison.

#### MORISON LECTURES IN EDINBURGH.

The first of the series of Morison lectures for the current session was summarized in these columns last week. The second and third lectures were delivered by Dr. Blackhall-Morison in the hall of the Royal College of Physicians, Edinburgh, on October 16th and 17th. Sir Robert Philip, President of the College, occupied the chair. In the second lecture Dr. Blackhall-Morison referred to psychology as an aspect of biology, commented upon the full growth of the Greek mind, and discussed especially the views of the Scottish philosophers, Brown, Hamilton, and Bain. The lecturer regarded sight and hearing as the master senses of man, and considered language as the result of external influences acting upon an innate aptitude in the human species, which had placed man in a class apart. He discussed the question whether mind is a living organism or merely a neural habit; and came to the conclusion, which was as old as Aristotle, that the mind was an active, living organism, connected with its parent organ, the brain, and possessed of properties of reproduction and metamorphosis as a natural process. He referred to the persistence of the human ego, and the views of transcendentalists like Herbart and Lotze. Experimental psychology was a special development of the study of the mind during the period with which he dealt. Recently there had been a new psychology specially associated with the names of Freud and Jung; this together with psycho-analysis he considered and criticized. In the third lecture he dealt with the mind diseased. He described the old views on psychiatry and the original primitive conditions for dealing with insane patients. He then dealt with the Act of 1774, the private madhouses, and the establishment of Commissioners

patient led to an unsatisfactory induction, and a case that gave trouble during the induction period was apt to be a case which would cause anxiety during the course of the operation. The psychology of the surgeon had also to be borne in mind. It was an advantage to know the man with whom the anaesthetist was working, his methods and his temperament. During the past week he had been attending the meetings of that and other Sections, and until Sir William Wheeler spoke that day he had not heard one word said on the subject of oil-ether colonic etherization. He was convinced that in certain cases that method was of extreme value. Used in high ether percentages, undoubtedly it had given rise to unfortunate effects—primary respiratory failure during the course of anaesthesia, or proflitis of greater or less severity, sometimes with the passage of blood per rectum within the consequent forty-eight hours. These dangers could be avoided almost entirely by the use of the control method in which the strength of ether in the standard solution was 50 per cent, the vehicle being olive oil. The success of the method depended on a rigid adherence to technique. The patient was weighed, as weight was the governing factor in regard to dosage. The dose to be administered by the bowl was one ounce of the standard 50 per cent. solution of ether in olive oil for every twenty pounds body weight of the individual; thus, a ten stone patient received seven ounces of the mixture. On the night preceding operation the bowel was thoroughly washed out, and on the morning of the operation a simple enema was given and the patient left as far as possible at rest. At least an hour before the time fixed for operation, morphine grain 1/6, with atropine grain 1/100, was administered hypodermically; this was omitted in the case of children and of those who were dull, lethargic, or comatose. A few minutes after the hypodermic injection had been given the ordered quantity of oil-ether mixture was passed slowly and continuously into the colon through a soft rubber catheter connected with a tube and funnel. The catheter should be passed as high as it would travel without force. The injection should be completed in about half an hour. Should the patient be restless or excitable two drachms of paraldehyde might be added to the oil-ether mixture. The catheter was then disconnected from the tube and funnel and left in situ. The patient was left at rest, the bed was screened, and the blind pulled down, the nurse in attendance keeping within easy reach, but preferably out of sight. Usually the patient became drowsy rapidly, sometimes muttering in an amiable confusion, and passed into a light sleep. Half an hour after the injection had been completed the anaesthetist approached as noiselessly as possible, some minimum of oil of orange in absolute alcohol (ol. auranti 25 per cent., alcohol absolute 75 per cent.) were dropped on the pillow to mask the pungency of the ether vapour, and followed by a few drops of ether. The upper sheet was gently drawn up to form a tent and the patient inhaled an ether-laden atmosphere until the onset of stertor. This usually took about four minutes. When stertor was established the patient was lifted on to the trolley and conveyed to the theatre—anaesthesia generally being deepened during transit. He was moved to the table and the operation began. By that time he had settled down to a placid anaesthesia, characterized by an absence of mucous secretion and venous congestion. But it was an anaesthesia which tended to lighten as time went on. In this lay its safety; the method was under control. Sooner or later symptoms supererogated calling for more anaesthetic, such as phnomia, twitching of the muscles of the face, movement of a limb, or reaching movements in cases in which there was any traction in the throat. A few drops of ether applied to the pillow tipped the balance and placidity was restored. When the operation was completed the bowl was washed out, and when that was done 2 oz. of olive oil should be injected into the colon and the case left at rest. By that time he had passed into a state of anaesthesia which continued for some hours after operation. The class of cases to which the method was applicable comprised the general surgery of the head and neck, growths, innocent and malignant, within and around the buccal cavity, glands in the neck, and, in an especial degree, goitres, plastic operations on the face and neck; throat and

nose operations, radical operations on the sinuses, cranio-tomy, exploration of the brain, cerebral and cerebellar growths, Gasserian ganglion operations, and breast cases. Mr. James A. McCosker (Dublin) observed that Mr. Trotter believed that chloroform was indicated for operations on the brain, mouth, neck, breast, and spine, and he implied that no other anaesthetic was as satisfactory from the surgeon's point of view. Since Boyd introduced his modification of Greenham's method of colonic anaesthesia by ether, Mr. McConnell had used his method combined with local infiltration in every case of brain tumour, in removal of the Gasserian ganglion, in diathermy of the mouth, tongue, and pharynx, goitres, amputation of the breast and mammary, and he could say emphatically that it was better than any chloroform anaesthetic, no matter by whom administered, and, moreover, it removed much anxiety during and after the operation. They had been using small doses of pure magnesium sulphate subcutaneously as a preliminary to anaesthesia, with strikingly good results.

Mr. FRANK COTTELL (Gloucester) said that to his mind the greatest importance should be attached to the necessity of co-operation between the surgeon and anaesthetist. Excluding, of course, all those cases of minor surgery, in which local anaesthesia had such a large field of usefulness, there was no doubt that the anaesthetist should be present whenever more major procedures are undertaken with local anaesthesia, whether by infiltration of the local area, or the method of paravertebral injection of nerves was employed, or nerve-blocking was pursued. There was plenty for the anaesthetist to do, even if no general anaesthetic at all was administered, for instance—the always put a great stress upon the necessity of the blood pressure being carefully watched every fifteen minutes. A very valuable alarm could be given in the event of the fall of blood pressure to any degree in the neighbourhood of 50, and other treatment could be applied before evil signs showed themselves. In a general way all his cases received an injection of morphine grain 1/6, with scopalamine grain 1/100, an hour before the time of operation. In fact, stuffed-up people, or those of a bronchitic type, an addition of atropine grain 1/200 was made. The infiltration of novocain, 1/4 per cent. or 1/2 per cent., according to the case, was then administered—100 c.cm. of this with 10 minims of adrenaline solution 1 in 1,000 could be used without any ill effects; general anaesthesia of a very light nature was given just prior to the patient being taken into the theatre. He maintained that in all prolonged operations the three elements of danger were bleeding, sepsis, and the anaesthetic, and the reduction of these to the minimum constituted the stronghold of success. One argument against this plan was the trouble and time taken in these preparations and the strong possibility of danger. One argument against this plan was the trouble and time taken in these preparations and the strong possibility of danger. One argument against this plan was the trouble and time taken in these preparations and the strong possibility of danger.

generally suitable for our requirements, at least in the province of surgery. It is of course quite possible that the difficulties which have arisen are felt with special force at the London Hospital, or are even peculiar to myself. But in any case they are real difficulties, and form a serious criticism of the whole system.

Withdrawal from private practice has necessarily a marked effect upon the mental outlook of the medical man. It narrows his horizon to the wards and laboratories of his hospital, and the difficulties and requirements of work in the outside world must in time be forgotten. The more complete the organization of his work, the more perfect the assistance he receives, the more will he tend to rely upon the mass of information placed before him and the less upon his own observation and interrogation of the patient. The diagnosis of a fracture will tend to become a matter of *x* rays, and a gastric case will only appeal to him as a source of test meals and opacities. Dealing as he does with patients of low mental power he is apt to feel that interrogation would only mislead him, whilst his estimate of the reaction of his patient to treatment will be quite inapplicable to individuals of another mental calibre. And yet he is teaching men who will have to cope with the very difficulties which his own surroundings tend to obliterate.

Again, one is apt to forget that a medical student does not walk the wards of a hospital entirely to learn medicine and surgery. He goes there in order to learn the practice of a profession of which technical knowledge is only a small part. It is his business to learn how to deal with human beings who are ill, and no small part of that business is to discover those from whom he may best obtain assistance when he is out in the world and on his own responsibility. Surely it is an impossible handicap to his teacher to limit him to the treatment of one class and to forbid him to consult with his old pupils.

It might, however, be supposed that in research at least the whole-time man would be safe, and I must say that for myself this was the one great attraction of the unit system. My experience has unfortunately brought disillusionment. Not only have I found my time absorbed in a routine the responsibilities of which it was impossible to devolve, but the very material for clinical study has eluded me. The clinical researcher depends for his material not upon the casual entries of the hospital, but upon cases sent to him from outside practitioners who know his special interests. Here at least I felt secure. The stream had always come; surely with more beds it would continue and expand. Instead of doing so it dwindled and sank to nothing. Apparently practice is too complex a thing for it to be possible for a practitioner to send his private patients to one consultant and his hospital cases to another. At any rate, I found myself with empty beds and no waiting list, appealing to my colleagues for cases to fill my wards. Moreover, a return to private work last year immediately brought a return to the old conditions, and the special cases which are so essential to research and to teaching began again to appear.

The unit system is said to have been borrowed from the Continent, but the position of a professor of surgery in a Continental clinic is entirely different. On the one hand he is the absolute and undisputed head of the whole clinic, including its laboratories, *x*-ray, and electro-therapeutic equipments. On the other hand, not only does he engage in private practice but he is the acknowledged leader of his profession, and all the most important and exceptional surgery of the district naturally passes through his hands. It is easy for him to organize through his assistants clinical demonstrations on the grand scale, and the teaching of surgery can be placed on a systematic basis which we have never achieved. But in most cases the teaching of the Continental student is limited to the lecture theatre; he may never enter the wards, and he rarely sees an operation. The personal touch of ward teaching, the close contact with his teacher which it affords, and its unrivalled opportunities for the direct study of the patient, are altogether lost, and the product of the system is more likely to be a brilliant student than a useful doctor.

In my opinion the teaching of surgery in this country is rather a cause for pride than for dissatisfaction, and no great revolution in its methods is required. But as surgery

becomes more and more complex and its demands every day become more exacting, it is only reasonable that the teacher should have at his disposal the organized help of younger men. This has been our aim at the London Hospital, where to each of the five surgical firms a paid assistant has been attached. Each firm consists of a senior and a junior surgeon, and an assistant who is paid £400 a year for services on the basis of scheduled time. His duties will be to assist in the organization of teaching and in research, and only in exceptional circumstances will he be called upon to undertake the ordinary routine of hospital work. In this way we hope to improve our teaching, while preserving its personal basis, and to train up a group of younger men whose outlook extends beyond the horizons of to-day. And we hope to produce a combination of effort from our whole surgical staff such as may worthily maintain the great traditions of our hospital.—I am, etc.,

London, W., Oct. 18th.

H. S. SOUTAR.

### SPASM OF THE LARYNX.

SIR,—In the discussion on spasm of the larynx reported in the *BRITISH MEDICAL JOURNAL* of October 20th (p. 712) Sir J. Dundas-Grant is stated to have said, in referring to laryngeal vertigo, "This has generally been attributed to a sudden congestion of the nervous centres produced by the pressure resulting from the expiratory effort accompanying the cough." He then proceeded to state that according to his view the symptoms are really due to syncope. This I pointed out so long ago as 1884, and I would refer those interested to the *Transactions* of the Medico-Chirurgical Society of Edinburgh, vol. iii, or my book *Diseases of the Throat, Nose, and Ear* (third edition), pp. 227-28. I quote from the latter:

"The act of coughing consists of a deep inspiration followed by attempted expiration with partially closed glottis. In laryngeal vertigo, however, the closure of the glottis is complete and the whole expiratory effort is felt through the air contained in the lungs by the alveoli, the large blood vessels in the thoracic cavity and the heart itself. As a result syncope—or a tendency to syncope—is produced, and almost at the same moment the spasm of the glottis relaxes and the attack is over."

Although Sir J. Dundas-Grant has suggested a different and I think mistaken mechanism, the result arrived at is the same—syncope. I was therefore not a little surprised at his remarks, as I have had every reason to believe that the explanation of the phenomenon I suggested in 1884 has been generally accepted.—I am, etc.,

Harrogate, Oct. 20th.

P. McBRIDE.

### ANTE-PARTUM HAEMORRHAGE DUE TO PLACENTA PRAEVIA, ASSOCIATED WITH ALBUMINURIA AND ECLAMPSIA.

SIR,—It is to be hoped that Dr. Lionel W. Bradshaw's memorandum (October 20th, p. 717) on his experience of the above condition will attract widespread attention, both because it is an interesting piece of evidence bearing on the question of the etiology of eclampsia, and also because it admirably exemplifies how observations and records made in the routine course of general practice may help scientific research.

To be appreciated fully, Dr. Bradshaw's note must be read in the light of the views on the etiology of eclampsia propounded in 1914 by my friend and colleague Dr. James Young.<sup>1</sup> Briefly, his view is that the toxins producing albuminuria and eclampsia are formed by massive necrosis of separated portions of the placenta, absorbed into the mother's blood through the unseparated portions. The association of albuminuria and accidental haemorrhage is a commonplace, and the usual interpretation placed upon it is that the haemorrhage and premature separation are due to the toxæmia. Young's view is that this is placing the cart before the horse, and, whether it may ultimately prove to be right or wrong, his view is certainly supported by cases, of which several have been observed in the Edinburgh Royal Maternity Hospital, in which the albuminuria has not developed until after the partial separation of the placenta had manifested itself by haemorrhage. Moreover, where the haemorrhage is followed by labour within a few

<sup>1</sup> *Trans. Edin. Obstet. Soc.*, vol. xxxix; Abstract, *BRITISH MEDICAL JOURNAL*, 1914, vol. i, p. 653.

The following technique has been evolved from personal experience of the method:

### Technique.

The patient's head is shaved. If the patient is excitable, timorous, or unlikely to stay quiet during the procedure, he is given rectal anesthesia by Boyd's modification<sup>1</sup> of Gwathmey's method. We have found this necessary on two occasions only; local anesthetics is the routine. The table should have a comfortable head-rest rather than a pillow. A point (A) if inches behind the external auditory meatus and 1 1/2 inches above Reid's base line is marked on the side to be injected. On the opposite side of the skull a point (B) if inches behind the external auditory meatus and 2 1/2 inches above Reid's base line is marked. A vertical incision two inches long is made deep to the scalp is infiltrated at these two points with 0.5 per cent. novocain solution. A middle point; this incision goes down to the bone. The bone is cleared with a periosteal elevator, and a mastoid retractor keeps the edges of the wound apart. The skull is perforated in the middle of the incision by Hudson's drill, or by de Martet's trephine, and a small opening is made in the dura mater. At the point B, on the opposite side of the skull, an incision

Fig. 3.—Coronal section of head with instrument in position.

For description see text.

Fig. 4.—Coronal section through posterior horns to show coronal relation of tentorium cerebelli. When a large tumour is present below the tentorium the latter becomes dome-shaped.

In the earlier cases the instrument depicted was not used, the ventricle being punctured freehand in the usual manner; it was soon found that the movements of the syringe and the necessary manipulations of the patient's head made it extremely difficult to keep the cannula steady in the ventricle, which was sometimes lost after the withdrawal of a small amount of fluid. The instrument<sup>2</sup> was made for me primarily in order to keep the cannula steady; incidentally, it is useful as a guide to the introduction of the cannula, for the latter is directed inevitably towards the point of the drill. Keen, in 1884, described the points on the surface of the skull at which a needle may be introduced and to which

aspiration or injection. may take nearly an hour, but no haste is permissible during aspiration the blood pressure falls, during injection it rises. It is for this reason that a small syringe is used and perhaps a minute is taken to fill it. When the injection is completed the patient lies with the injected side up, and is taken to the x-ray room. The patient then inclines his head towards the side of injection so that air gets through to the anterior horn of the opposite side. He is then told to look straight up at the ceiling and another radiogram which outlines the anterior horns of both ventricles is taken. Rotation of the head is again carried out in order to feed all the air into the opposite ventricle, a photograph of which is then obtained. When air is present in both anterior horns rapid adoption by the patient of the prone position allows the air to reach both posterior horns, which can be photographed. Sufficient information is usually obtained by radiograms of each lateral ventricle and of the anterior horns. The whole procedure may take nearly an hour, but no haste is permissible during aspiration or injection.

In the earlier cases the instrument depicted was not used, the ventricle being punctured freehand in the usual manner; it was soon found that the movements of the syringe and the necessary manipulations of the patient's head made it extremely difficult to keep the cannula steady in the ventricle, which was sometimes lost after the withdrawal of a small amount of fluid. Keen, in 1884, described the points on the surface of the skull at which a needle may be introduced and to which

It should be directed in order to reach various portions of the lateral ventricle.

### Difficulties in Technique.

It is essential at the outset to be certain that the piston of the syringe is a perfect fit and that the cannula is as accurately adapted. I have the cannula specially ground to fit the nozzle of the syringe, otherwise air enters the syringe during withdrawal of fluid or air escapes at the ventricle is unknown. A short rubber junction between the syringe and cannula is used if the ordinary junction is not airtight. The length of the cannula should be 5 in., but when the instrument is used it should be 2 in. longer. Apart from faults in the syringe and cannula there are two difficulties. (1) After insertion of the cannula no cerebro-spinal fluid appears; this may be due to distortion of the ventricle or to occlusion of the part of it aimed at. When a large tumour is present in the posterior cranial fossa it sometimes pushes up the tentorium cerebelli and presses on the occipital lobes of the brain so that the posterior horns on one of both sides are reduced to mere slits and their junction with the body of the ventricle may be displaced upwards. In such a case an attempt to puncture the posterior horn or to enter the ventricle opposite the trigonum ventriculi may fail as the cannula may pass below the cavity. If the cannula be directed more upwards than usual on a second attempt the ventricle may be found. If

The instrument is made by Mr. Edwin Haines, Dublin, the cannula by Messrs. Allen and Hanbury.

During aspiration the blood pressure falls, during injection it rises. It is for this reason that a small syringe is used and perhaps a minute is taken to fill it. When the injection is completed the patient lies with the injected side up, and is taken to the x-ray room. The patient then inclines his head towards the side of injection so that air gets through to the anterior horn of the opposite side. He is then told to look straight up at the ceiling and another radiogram which outlines the anterior horns of both ventricles is taken. Rotation of the head is again carried out in order to feed all the air into the opposite ventricle, a photograph of which is then obtained. When air is present in both anterior horns rapid adoption by the patient of the prone position allows the air to reach both posterior horns, which can be photographed. Sufficient information is usually obtained by radiograms of each lateral ventricle and of the anterior horns. The whole procedure may take nearly an hour, but no haste is permissible during aspiration or injection.

It is essential at the outset to be certain that the piston of the syringe is a perfect fit and that the cannula is as accurately adapted. thickened, and the lung non-expansile; a chronic effusion then results with a great probability of the subsequent development of a tuberculous empyema, especially after frequent tapplings.—I am, etc.,

London, W., Oct. 22nd.

F. G. CHANDLER.

SIR,—The case of pleural effusion described by Dr. McOscar of Buxton recalls to my memory a case which came under my care in 1911, when I was assistant medical officer in the Central London Sick Asylum, Hendon, N.W.

On returning from a holiday in June of 1911, I found a male patient in one of my wards looking rather cyanosed and breathless. He had not complained to either doctor or nurse, during my absence, of any condition requiring treatment. He suffered from phthisis, but was on full diet and did light work about the ward and in the grounds. I found dullness of the left side up to the clavicle. The same day I aspirated him with a Potain's aspirator and drew off 156 ounces of fluid before he began to cough slightly. It was, I recollect, a matter of regret to me that I could not get another 4 ounces.

Some six weeks later I drew off 65 ounces, and early in November, just before I left that institution, I again emptied his chest, on this occasion removing 56 ounces. Owing to changes in the staff and to my absence from London, I heard no more of the case until September, 1914, when I was informed that the man had taken his own discharge, in August, 1914, and was then considered to be practically free from any phthisis—in fact he was understood to have joined the army.

I have not heard of any greater amount being removed from the left pleural cavity.—I am, etc.,

JAMES OAG, M.A., M.B., Ch.B.,  
Senior Assistant Surgeon,  
Wigan Infirmary.

October 22nd.

#### THE TREATMENT OF TUBERCULOSIS BY THE SPÄHLINGER METHOD.

SIR,—I should like to add my testimony to that of Dr. Thomas Watts, M.P., and of others who have at various times written and spoken upon this subject.

Last August, in company with several professional colleagues, all of them particularly interested in tuberculosis, I spent a medical holiday in Switzerland. The first week we attended the admirable course of lectures and the clinical and special demonstrations arranged for the conference by Dr. Rollier at Leysin. We there saw some of the wonderful results obtained in surgical tuberculosis through the agency of heliotherapy combined with a return to natural conditions. It is not, however, with our Leysin experiences that this letter is concerned. From Leysin we went to Montana at the invitation of Sir Henry Lunn. Here we visited several sanatoriums for pulmonary tuberculosis and were informed by Dr. Bernard Hudson, the medical superintendent of the Palace Hotel Sanatorium, of several cases which he had successfully treated with Spählinger's serum. Dr. Stephani, the proprietor of another sanatorium in Montana, was even more enthusiastic about the beneficial effects of the Spählinger treatment upon a considerable number of his patients. We had the good fortune to meet M. Spählinger one evening at the Palace Hotel, and he invited us to Geneva to inspect his laboratories and to see some of the treated patients. Several members of the party availed themselves of the opportunity. We were, one and all, impressed by M. Spählinger's bacteriological knowledge and by the freshness and originality of his ideas and methods. He told us the broad principles of the preparation of his serums, showed us all over his laboratories, which are as well equipped as any that we had seen, and moreover contain many ingenious devices which all testify to his originality of thought. He has a staff of ten assistants and laboratory attendants, all of whom he pays out of his own pocket. Not only has he refused fees from patients, as Dr. Watts states in his letter, but I am credibly informed that his researches during the past twelve years have swallowed up the whole of his father's, his wife's, and his own fortunes, and that unless substantial financial aid is forthcoming by the end of the present year the whole establishment must close down.

M. Spählinger showed us his experimental animals (horses, cows, monkeys, rabbits, guinea-pigs, etc.), and among them a cow which he had immunized against tuberculosis, and had subsequently inoculated with living

tubercle bacilli, without harming the animal. He took us round Geneva to see several former patients whose history, temperature charts, and x-ray photographs showed that they had been profoundly ill with phthisis, and as a result of his treatment were now cured and carrying on their avocations in various business establishments. Several tuberculosis officers were members of the party and examined the patients, who, they all agreed, were apparently cured of their active phthisis.

The profession is always jealous, and rightly so I think, of the activities (in the domain of medicine) of non-medical individuals, but one can recall several instances where scientific work of the highest order and importance to medicine has been done by non-medical persons. Pasteur, the founder of modern bacteriology and one of the greatest benefactors of mankind, was not a doctor; several of our biochemists are not medical men, and there is at least one radiologist in London who is not a medical man, whose work is as excellent as that of any medical radiologist. The work which M. Spählinger has accomplished and is still doing may be in the same category.

The problem of consumption and of tuberculosis generally is one of international importance, and in spite of all the advances in prevention and treatment that have been made in recent years it is notorious that there remains an appalling amount of mortality, morbidity, and invalidism, to say nothing of the economic wastage, resulting from the ravages of the tubercle bacillus. Scientific medicine does not recognize national boundaries and frontiers. It seems to me that a problem of this magnitude and international importance should be investigated—and at once—by a small international commission of experts. International financial aid should be given to M. Spählinger so that he may proceed forthwith, unembarrassed by financial difficulties, with the preparation of his serums and vaccines on an adequate scale for extended trial in various countries. The money that would be required would be small compared with the enormous economic cost of the mortality and invalidism resulting from tuberculosis, to say nothing of the toll of human suffering which it exacts. In the event of M. Spählinger's claims being substantiated, he will indeed prove to be a benefactor of mankind, and his idealism will be justified.—I am, etc.,

DAVID NABARRO.

London, W., Oct. 15th.

SIR,—It is, as Dr. Cheater points out in your issue of October 20th, an honourable tradition in the profession that whosoever discovers a new remedy or improves upon an old one should publish his theory and technique. The tradition has been established in the interests of the public, but if it should happen that the interests of the public are better consulted by a temporary withholding of details, then the tradition should clearly remain unobserved. This attitude was very properly and wisely adopted in the case of insulin, and if it had been adopted in some other cases it might have been better for the credit both of the work and the worker. I am one of those—and they are many—who have strongly advised M. Spählinger not to allow himself to be beguiled into a premature disclosure of his complete technique. Such disclosure should in our view be delayed until a standard has been established, and this cannot be done until the complete serum and vaccines are again in being and their efficacy demonstrable. To adopt any other policy would in our view be to court disaster. There would be nothing to prevent unscrupulous persons from exploiting worthless nostrums, said to have been made according to the Spählinger methods—which has indeed even now been done.

My friend Dr. Watts is perfectly right in saying that there is no secrecy. The serum is a horse serum prepared in a particular way and taking four years to make; the vaccine is an ordinary vaccine prepared from the whole bacillus—fatty envelope and all. Spählinger's work is merely an evolution along well established lines and according to generally accepted principles. But he wisely withholds the details of his technique for the reasons above stated. It would be contrary to the public interest were he to explain them at this juncture.

I know nothing about M. Spählinger's dealings with the

# II.—GEORGE JEFFERSON, M.S., F.R.C.S.,

Assistant Surgeon, Salford Royal Hospital; Lecturer in Applied Anatomy, University of Manchester.

No one can deny a careful consideration to any method which will allow increased accuracy in the localization of cerebral tumours. It is claimed that in ventriculography (or "cerebral pneumography," as its inventor, Dr. Dandy of Baltimore, now calls it) we have such a method. Our purpose in this discussion will best be served, perhaps, by examining the question under three headings: First, what is claimed for ventriculography? second, from a consideration of the general physical characters of intracranial tumours what help might we be justified in expecting from it; thirdly, my own experience of the matter.

First, then, what is claimed for ventriculography? By the replacement of intraventricular cerebro-spinal fluid by air and subsequent x ray we are able to obtain the outline, the shape of the lateral ventricles. With good technique the size and contour of the ventricles can be quite clearly seen in the majority of cases, and when a tumour is present changes in ventricular size, shape, and position give valuable information. It is claimed that the

We can, however, in some measure, reconstruct the progress of the case from this specimen and see how the tumour blocked the exit of cerebro-spinal fluid and gave rise to a slowly increasing internal hydrocephalus, great enough to expand and thin the skull-cap and open the sutures. The mechanism of production of this hydrocephalus is usually either by crowding of the cerebral lobes on to the roof of the fourth ventricle, so interfering with its permeability, or by occluding the foramina of Luschka and of Magendie. Alternatively the tumour may force with the free passage of cerebro-spinal fluid (as in Figure 2, a cerebellar tuberculoma). Speaking generally, when we have a bilateral internal hydrocephalus we have very strong evidence that the tumour is in the posterior fossa and must be sought there. Tumours of the mid-brain

FIG. 2.—Tuberculoma of cerebellum showing distortion of the fourth ventricle.

and pons will also frequently block or distort the aqueductus syli but they do not (save the rare pineal growth) give much difficulty in localization. This obstructive hydrocephalus may give rise to expansion of the floor of the third ventricle, to opening up of the sella turcica or actual erosion of the dorsum sellae, and to minute hernial protrusions through the dura, examples of all of which I have personally seen. Now as regards tumours of the hemisphere. It may be asked what happens to the lateral ventricle when a tumour is situated in a hemisphere. It is obvious that a hydrocephalus will no longer result, rather the reverse. An examination of pathological specimens soon discloses the fact that most hemispherical tumours cause a dislocation and often a deformity of the corresponding lateral ventricle. This is clearly seen in Figures 3 and 4. In the former, one ventricle is seen to be almost obliterated by a large glioma; the other is rather larger than normal, possibly because the tumour, has embarrassed the outflow from the opposite ventricle at the foramen of Monro. The ventricular distortion is extreme in this case, but varying grades can be seen in other cases. [Further lantern slides were shown illustrating these points.] When a tumour is present it is the rule that the hemisphere containing it to be larger than its fellow. This increase in size is not due as might be thought purely to the additional mass given by the growth itself, but is due in addition to secondary oedema. This point is a most important one and has not, I think, previously received much attention. It was first brought forcibly to my notice in the case of a man who died rapidly in coma without any operation being performed. At the autopsy, which I performed myself, a small tumour

The information obtainable by means of ventriculography depends primarily on our recently acquired knowledge of the secretion of the cerebro-spinal fluid and the pathways which it follows. We know that any obstacle to the flow of the cerebro-spinal fluid from its point of secretion in the choroid plexuses to its absorption through the arachnoid villi into the venous sinuses will result in an obstructive hydrocephalus. As far as concerns tumours we may

## II.

have its greatest utility. It is frankly not known, that ventriculography would not be of doubtful or where (more rarely) its position as the early ones. It is in cases where the precise location of brain tumour are by no means such good surgical risks But if we are to wait we must remember that late cases of tumour are so gives unequivocal localizing signs. Increases in size often comes to involve eventually important structures and so gives unequivocal localizing signs. watched, for a tumour which lies in a silent area as it accurate localizations will be made the longer the cases are still of various clinicians. In this connection the time element is of some importance. A larger proportion of clinical means will vary in different hands according to the Obviously the percentage of correct localization by purely is likely to result from the pursuit of this question. truth, so debatable that nothing but mutual rectification cases, but admits that this is a debatable point. ## Obituary.

### WILLIAM EDWARD ASHLEY CUMMINS, M.D., M.Ch.,

Professor of Medicine, University College, Cork.

WITH the death of Professor W. Ashley Cummins of Cork on October 18th after a brief illness, a great figure in Irish medical education passes away, and his loss will be mourned, not only in the city and county where his life of service and devotion was spent, but by Cork graduates all over the world. The eldest son of the late Dr. William Jackson Cummins, Ashley Cummins was born at Blackrock, Cork, in February, 1858. He entered Queen's College, now University College, and soon distinguished himself both as a keen sportsman and a successful student. His performances in cycle racing and in the football field brought him to the front rank in College games, and finally he secured his cap in International Rugby football, playing for the Irish team in 1879, 1881, and 1882. He was also a keen yachtsman and his wonderful knowledge of the intricacies of wind and tide in Cork Harbour gained him many victories and made him famous amongst the yacht-racing fraternity of Queenstown.

But with all his success at sport, he was at the same time devoting himself with untiring energy to his work and laying the foundations of the singular clinical acumen and skill which was to distinguish him in his professional career. In 1879 he took the M.D., M.Ch., and L.M. of the Queen's University of Ireland with First Class Honours and the Gold Medal, and he gained the L.A.H. Dublin in the following year; he was the Senior Scholar in Surgery and an Exhibitioner of Queen's College, Cork. After holding a house appointment he started practice in his native city, and his success was assured from the first. With increasing experience his clinical skill rapidly matured and his practice grew to such considerable proportions as to strain his great fund of energy to the utmost. But, while he loved his practice, it was in the teaching of clinical medicine that he found his greatest delight and success. His bedside demonstrations at the Cork Union Hospital were things to be remembered, and they drew an ever-increasing number of students to that institution, which soon received University recognition as a centre for clinical instruction.

When, in 1897, he became Professor of the Practice of Medicine at University College, Cork, he found the greatest interest of his life in an appointment which gave him full scope for his special bent. It is safe to say that his remarkable powers as a teacher proved the source of inspiration to many a Cork student since distinguished in his profession; and his high character and self-forgetting devotion to duty made him beloved and respected by all.

Though so much occupied by the claims of teaching and practice, he still found time to take a prominent place in the professional life of the city and, indeed, of Ireland. He was at one time President of the Cork Medical and Surgical Society, and was also ex-President of the South of Ireland Branch of the British Medical Association. He was senior surgeon to the County and City of Cork Hospital for Women and Children; senior medical officer Cork District Hospital; consultant physician to the Lying-in Hospital, the Eye, Ear, and Throat Hospital, and the Home for Incurables, Cork; examiner in medicine to the National University of Ireland, and, at one time, examiner in medicine to the Apothecaries' Hall, Ireland. With all this, his

interest in College sports never flagged, and his love of Rugby football was a bond that kept him in close touch with the students of all the Faculties of University College, Cork.

He married, in 1884, Miss Jane Hall, daughter of the late Mr. Robert Constable Hall of Rockliffe, co. Cork; and it was in his family life that he revealed the most beautiful and lovable side of his character, a precious memory to those now left to mourn his loss. He leaves a large family of sons and daughters, of whom several, including Dr. Robert C. Cummins, Dr. N. M. Cummins, Dr. Ellice Hearn, and Dr. Grace Cummins, have embraced their father's profession. All his six sons served in the European war, two gaining the Military Cross for gallantry, and two fell in action. His brother is Colonel S. Lyle Cummins, A.M.S.(ret.), David Davies Professor of Tuberculosis in the Welsh National School of Medicine, Cardiff.

The sympathy of all who knew him will go out to his wife and children in their hour of sorrow; but they should take comfort in the thought that the work and example of Ashley Cummins will not soon be forgotten.

PROFESSOR W. E. A. CUMMINS.

Dr. R. H. POWERS of Southend-on-Sea died on Sunday, October 7th, after an attack of lobar pneumonia that lasted only three days. Born in 1868, Richard Henry Powers was educated at Cheltenham College and St. Mary's Hospital, and obtained the English Conjoint diploma in 1898. He practised at Brigg till 1910, when he joined Dr. Sellors in partnership at Southend-on-Sea. During the war—unfit for active service—he was unwavering in his attendance at the Glen Auxiliary Hospital and in the care of troops under his medical charge. An overflowing congregation at the funeral service, including detachments of the 28th and 34th British Red Cross and St. John's V.A.D.'s, and a numerous gathering of local medical men and nurses, testified to the esteem in which he was universally held. Dr. Powers's unselfish and unceasing devotion to his work remains an inspiring memory. He leaves a widow, daughter and son.

Dr. ALBERT THEOPHILUS DUKA, D.S.O., late Major R.A.M.C.(T.C.), died at New Milton, Bournemouth, in September, aged 57. He was educated at Cheltenham College; at Cambridge, where he graduated B.A. in 1888 and M.A. in 1892; and at St. George's Hospital. He took the L.S.A. in 1891, and the M.R.C.S. and L.R.C.P.Lond. in 1892. He afterwards went to Australia, and accompanied the Australian forces to South Africa, where he served as medical officer of the Queensland Mounted Infantry, was mentioned in dispatches and gained the D.S.O. at Eland's River; he received also the Queen's Medal with two clasps. In August, 1914, he rejoined the army as a temporary lieutenant in the R.A.M.C., became captain after a year's service, and major on September 26th, 1915; he served in the advance on and retreat from Mons, and later in England, in charge of the clearing hospital at Eastleigh. After the war he served in the Ministry of Pensions department at Southampton till his death. He was a member of the Bournemouth Town Council, and a prominent local Freemason, being a past Worshipful Master of Boscombe Lodge.

We regret to record the death, on October 2nd, of Dr. GEORGE LIVINGSTONE MITCHELL, of Redditch, Worcestershire, from scarlet fever, contracted from a patient he was attending. Dr. Mitchell, who was only 29 years old, was

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology Westrand, London*; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER. (Advertisements, etc.), *Articulate Westrand, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera Westrand, London*; telephone, 2630, Gerrard. ### QUERIES AND ANSWERS.

"S. N. B." asks for references to clinical articles dealing with intravascular streptococcal haemolysis.

### TINTED LENSES FOR CATARACT.

"E. E. M." (Bournemouth) writes: By the "colour therapy" of cataract E. H. W. (October 20th, p. 737) may perhaps mean the provision of tinted lenses with a view to the exclusion of ultra-violet light. The comfort often experienced by cataract patients from tinted spectacles has been known to ophthalmic surgeons longer than I can tell, but the scientific basis for the prescription of Fieuzal or Crookes's glass has only been discovered in comparatively recent years. In America Dr. W. S. Burge and Dr. A. S. Neill published in 1915 some remarkable experiments with ultra-violet light, proving that the normal lens is, by virtue of its fluorescence, resistant to its ill effects. Healthy eyes therefore need no protection from ordinary daylight. When, however, a lens is immersed in a dilute solution of a calcium, sodium, or magnesium salt (all three of which are contained in excess by cataractous lenses) or of dextrose the natural fluorescence is reduced and the lens can no longer resist the opacifying effect of ultra-violet light. The conclusion is obvious that besides medical treatment directed to correct the constitution and increase the health of the lens some variety of anti-actinic glass should be worn, at least out of doors, in cases of early cataract.

### INCOME TAX.

#### *Deduction for Rent, Rates, etc.*

"A. H. L. T." is assessed in respect of a practice in the West End of London, and has been informed by the local inspector of taxes that the deduction in respect of rent, rates, lighting, etc., which has hitherto been on a basis of two-thirds, will be reduced to the basis of one-half.

\* \* Whether the alteration is justified depends on the exact facts of the case. Where the premises used for the practice are in such localities that exceptional rents have to be paid, an abnormally high proportion on is justified—in Harley Street, to take an extreme case. Perhaps the best way of approaching the question is to consider whether the remainder (one-third or one-half, as the case may be) of the rent, rates, etc., fairly represents the value of the private residential portion of the premises. The £4 legal expenses is not allowable if, as we assume, they were incurred in the initial hiring of the garage by "A. H. L. T."

#### *Partnership Receipts.*

"D. D."—A took B into partnership as from October 1st, 1922, on a one-third basis, which was increased to one-half as from January 1st, 1923. On October 1st, 1923, A retired and B succeeded to the whole practice. Each partner provided his own means of locomotion at his own expense. How should they divide the tax payable for the year ending April 5th, 1924?

\* \* A is liable on the basis of one-quarter of the gross average profits less one-half of a year's expenses of his own locomotion—less, of course, the personal allowances applicable thereto; and B is liable on the balance of the gross assessment less his personal allowances.

#### *Motor Car Transactions.*

"C. F. R." bought a second-hand T. car in 1917 for £150; he sold it in 1923 for £85, buying a new B. car for £540. What allowance is due?

\* \* The cost of replacement is the 1923 cost of a T. car of similar power and condition to the one purchased in 1917 (clearly a difficult matter to estimate), less the £85 received. To allow £540—£85 would involve allowing an outlay on improved equipment. The inspector offers an allowance of £260, which would

be right on the assumption that a similar second-hand T. car would cost £260+£85=£345—that is, more than twice the 1917 cost. We advise "C. F. R." to accept the offer.

### LETTERS, NOTES, ETC.

#### UNITED HOSPITALS WINTER SPORTS CLUB.

DR. J. DUNCAN LYLE, Maidenhead (Honorary Secretary of the United Hospitals Winter Sports Club), writes: I trust that you will assist me to bring this club to the notice of your readers. The club was founded to encourage winter sports amongst past and present students of all recognized medical schools in the United Kingdom. As the Grand Hotel, Griesalp, Bernese Oberland, was considered a success last season, it has been decided to make this the club hotel for 1923-24. Our President, Lord Dawson, has very kindly consented to give a trophy for a ski race at Griesalp between January 6th and 13th. Particulars can be obtained from the manager of the hotel.

#### HERPES, VARICELLA, AND "W. G."

DR. B. H. PAIN (Southborough, Kent) writes: I have a patient, a finely built man, aged 76, suffering from herpes zoster and also a mild attack of varicella. The herpes is all down the course of the great sciatic nerve and its branches, there being nine distinct patches of herpes: on the buttock, back of thigh, outside of leg and ankle, and a patch on the dorsum of the foot. He has had much pain down the leg, both before the herpes developed and after. When I first saw him the herpes was present and he had one typical varicella vesicle on the chest; I remarked at the time that if there had been half a dozen more vesicles like that I should call it shingles and chicken-pox. Some sixty or seventy vesicles have since appeared, and are now becoming covered with typical black scabs. Dr. Galbraith, M.O.H. for Tonbridge, saw this case with me, and agrees with the diagnosis. My patient was greatly indignant at the idea of chicken-pox, and said it was a ridiculous suggestion, so I was glad to be able to show him this week's JOURNAL, where Dr. C. H. Sedgwick relates a case of chicken-pox following herpes.

Strangely enough, he was very interested in "E. K.'s" query on the same page, asking if Dr. W. G. Grace, the cricketer, had "only one lung," for my patient had played for Gloucestershire (he thinks it was in 1877) with "W. G.", and when he read the query in the BRITISH MEDICAL JOURNAL he said, "I never heard Grace had only one lung. All I know is, he could roar like a bull." This I can corroborate, for when I saw "W. G." playing at Tonbridge against Kent more than thirty years ago, I remembered his voice could easily be heard all over the ground. In my experience people with "one lung" do not, as a rule, have powerful voices, even when their disease is arrested.

DR. A. LYNN HEARD (Bexley, Kent) writes: For long I could not understand the apparently epidemic occurrence of herpes zoster until Dr. Lefevre of Knysna, Cape Colony, called my attention some years ago to the connexion between it and varicella. The following cases have absolutely convinced me of the identity of the two diseases:

1. An only child had chicken-pox and was not isolated. Shortly afterwards her grandfather, living in the house, developed slight herpes in the left subclavicular region.

2. A lady and her daughter were for three months at a small Welsh watering place. The child arrived home with a rash. I saw her next day with well marked chicken-pox; no cases were known to have occurred in the watering-place and they had met but few people. Following up Dr. Lefevre's theory I asked the mother if she had had a rash and was told she had had a slight one a few weeks previously. Only by insistence did she let me see her back, as she assured me it was nothing. I found the undoubted remains of a mild herpetic rash under the left scapula.

3. An elderly gentleman developed severe herpes on the trunk on December 19th, 1921, as the result of visiting a friend so suffering. A small grandchild, aged 2, was staying in the house at the time. I foretold that in a fortnight it would develop chicken-pox, which duly came to pass on January 1st, 1922.

4. A lady had herpes of the perineum and pudenda and I said her child would have chicken-pox in a fortnight, which was likewise verified.

It is quite evident that the infection is one and the same—appearing usually as varicella in younger and herpes zoster in older subjects—both varieties being infectious. The fact that herpetic cases usually occur singly in households is no doubt generally due to the other members having had chicken-pox in early life.

#### A DISCLAIMER.

DR. H. L. WARREN WOODROFFE (Chester) writes: In the issue of the *Chester Observer* dated October 13th there appeared a letter entitled "Appreciation of the Infirmary," in which my name was mentioned. I wish to state that the letter was published without my knowledge or sanction.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, and 37 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 203.

remember that the best extinguisher is sand. He must not hesitate to puncture that sand-bag which the surgeon is going to use and scatter the sand over the flames! But I hope you will never see this really alarming danger.

Either is the ideal anæsthetic for the operation for complete removal of tonsils and adenoids. No chloroform should be used. After the child has been deeply anæsthetized by the open method, anæsthesia is easily maintained by means of pumping air, or passing oxygen, through a Woolf's bottle containing ether. This method has reduced the anxiety of the anæsthesiologist to a minimum. As this is the operation most frequently performed upon children, I must not omit to mention it and most strongly urge the use of this method. It has seemed to cause less saturation than other ethers, and I can recommend it for this particular operation.

The operation for which gas and oxygen is a peculiarly well suited anæsthetic is that for congenital hypertrophic stenosis of the pylorus. This baby is emphatically a started anæsthetic injury. Certain of our early cases died, twenty-four to forty-eight hours after operation, with vomiting and collapse, and, post mortem, extensive fatty degeneration of the liver was found. Now the Kammstedt operation lasts only from five to ten minutes, so that the amount of anæsthetic absorbed must be very minute, but such is the delicacy of these started infants that it was apparently sufficient irretrievably to damage their liver and to determine a fatal result. These operations have been performed with a far greater degree of success when gas and oxygen have been administered. Operations for intussusception also seem to do best under gas and oxygen. In the following tables I have summarized the results of all the operations for these two conditions which have been performed at the Great Ormond Street Hospital during the last four years, 1919 to 1922 inclusive, stating the anæsthetic administered.

| Congenital Pyloric Stenosis.            |               |                         |      |                         |       |        |           |        |           |

|                                         |               | Cases.                  | Per cent. | Cases.                  | Per cent. |  |  |  |  |
| Chloroform and ether, or gas and oxygen | 54            | 16                      | 29.5      | 17                      | 31.5      |  |  |  |  |
| ether                                   | 25            | 5                       | 20.0      | 5                       | 20.0      |  |  |  |  |
| Spiral .. .. .                          | 2             | 2                       | 100.0     | 2                       | 100.0     |  |  |  |  |
| Spiral + ether                          | 1             | 0                       | —         | 0                       | —         |  |  |  |  |
| Local .. .. .                           | 1             | 0                       | —         | 0                       | —         |  |  |  |  |

These tables certainly point to the advantage to be gained by administering gas and oxygen, and I am inclined to consider it the best anæsthetic for these cases. At present one cannot be more didactic on the subject of gas and oxygen, but perhaps at a later date a more definite statement may be made as to the use of this anæsthetic in a wider field. Ethyl chloride is a particularly useful anæsthetic for dental extractions in children, and I say without hesitation it is always the "anæsthetic of choice" when several teeth have to be dealt with. The only qualification I have

ADMINISTRATION OF THE ANÆSTHETIC.

No severe shock or strain to the central nervous system of a child should be lightly undertaken. Our art should ever be gentle and human; our aim with all our patients should be to make their memories of operations and similar awesome procedures as pleasant as possible. Some degree of apprehension and uneasiness is a necessary preliminary to operations; and this exists in the child's mind too, often at a surprisingly early age. In the child, happily, it is usually a simple fear of pain, and the feeling is usually allied by means of tact and that quality which can only be described as "child understanding." We all know what splendid patients children make so long as they are of unspeakable. Always explain. Never deceive. It has been my unfortunate lot to see many children who have suffered severe shocks from the terror due to a rough administration of an anæsthetic, or to an operation performed under "deceptive persuasions" rather than a properly administered anæsthetic. I verily believe that many of those children will have suffered permanent nervous damage, and certainly they will never again trust anyone approximately resembling a doctor. The blessed gift of unconsciousness should never be needlessly withheld from any of our patients. "But," you will say, "there is anæsthetic." True; but I want to try to make a few suggestions which will enable you, with tact and skill, to reduce that unpleasantness to a minimum. Gentleness, and understanding are the most necessary of all the possessions of a child's anæsthesiologist. A small child, unless frightened, is a most reasonable individual, and will accept and appreciate suitably worded explanations of the things that are about to be done to him. He should not have the initial fright, when entering the room or theatre, of seeing the surgeon's instruments exposed on his table. And I must here warn you against acceding to the oft-expressed wish of the fond parents, "Oh, do give the anæsthetic to the child in bed, and carry him to the operating room when he is under." It is a most dangerous proceeding, and should be strenuously avoided. Do not have the child in the room until the surgeon's instruments are ready and all is prepared for the operation to begin. Let the surgeon do the waiting. But do not risk the chance of having the child at that stage of anæsthesia when the surgeon may start, only to find that a delay occurs, and consequently the child has to have more anæsthetic than is absolutely necessary. When you have helped the child into the required position, coax him, do not force him, under. Explain that you want him to do—namely, to "breathe." There are many little ideas which will encourage him; a balloon exhibited, which he may be told can be blown bigger, may persuade him to blow more vigorously. And let him know that his effort of blowing he will blow the nasty stuff away; for this concentrating on his effort to blow the inspiratory action will pass unnoted so long as the ether is slowly administered. Put five to ten drops of essence of orange on the facepiece, covered with twelve to sixteen layers of gauze, and tell him it smells of oranges. This essence of orange is made with alcohol, and in half a dozen breaths

to make concerning its use is that, owing to the muscular spasm which it causes, there may be a little difficulty in holding the jaw forward. This difficulty is easily overcome; but it is of the utmost importance that a free air-way should be maintained, and any anxiety that the use of ethyl chloride may have caused has been invariably due to an insufficient intake of oxygen. My experience in many thousand administrations without the least anxiety enables me to make this statement with confidence. The embryonic state of the central nervous system in early life renders it possible for operation to take place without an anæsthetic if the tissue involved is also insensible; and I refer to the practicability of the rapid circumcision in the first two or three weeks of life. But such a procedure is possible only during that short period. The central nervous system develops rapidly in the early months, and, apart from the minor procedure referred to, the practice is to be deprecated.

juice contains altered blood, but the duodenal fluid is golden yellow, gastric ulcer is indicated; if, however, the gastric juice remains clear, while aspiration of the duodenal fluid yields blood, duodenal ulcer is probable; duodenal cancer causes prolonged bleeding. Einhorn's method may disclose occult blood, when the examination of the faeces is negative or the presence of haemorrhoids renders examination useless. Bacteriological examination of the fluid is important. - Normally, and also in hyperchlorhydria, the duodenal fluid is sterile; when the HCl content of the gastric juice is considerably reduced *B. coli*, staphylococci, *Streptococcus faecalis*, *B. proteus*, etc., may be found. In diseases of the biliary passages bacteria may be found in the duodenum, however acid the gastric juice may be. Einhorn's tube may be used for filling the duodenum with barium in suspension in cases of pyloric spasm or obstruction. Einhorn has also treated 315 cases of gastro-duodenal ulcer by passing food directly into the duodenum; the tube remained *in situ* for fifteen to twenty days.

## Surgery.

### 299. Narcosis for Operations on Infants.

P. DREVERMANN (*Munch. med. Woch.*, September 7th, 1923, p. 1153) points out the risks of the usual anaesthetics in infancy, when operations are necessary. He has therefore employed instead hedonal (methyl-propyl-carbinol-urethane) as a narcotic. The drug is given by rectal injection: deep sleep occurs, the respiratory volume is increased, and no bad effects follow. This deep sleep does not cause complete insensibility to pain, as do the usual anaesthetics; but the signs of pain were slight, and the younger the infant the less the signs of pain. The younger children showed signs of pain only for a moment and then slept again. The author has performed many operations during hedonal narcosis. In infants under 3 months, 0.75 to 1 gram of hedonal was given as a rectal injection; in children up to 18 months the dose was 1 to 1.5 gram by rectum. The drug was given in 30 c.c.m. of oatmeal water, and it is important that it should be well mixed with this fluid. The rectum should be washed out before the injection is given, and the nates pressed together for ten minutes afterwards, to prevent the injection fluid escaping. The sleep is deepest in an hour and a half. At this time the operation should be performed. The author divides his cases into two groups: (1) the youngest infants under 7 weeks old; (2) older children up to 18 months. In the first group operations (such as those for hernia, laparotomy, etc.) can be carried out in the hedonal sleep, and the risks of anaesthetics are thereby avoided. In the second group the hedonal alone was not sufficient; but if combined with an injection of novocain and adrenaline, as a local anaesthetic, operations could then be carried out. The author performs all operations in the first eighteen months of life without inhalation anaesthetics; he recommends hedonal narcosis for infants (especially very weak infants) in the first few weeks of life; and for older children a combination of hedonal narcosis with local novocain and adrenaline analgesia.

### 300. Periarterial Sympathectomy.

H. ELVING (*Finska Läkarsällskapets Handlingar*, July-August, 1923, p. 422) has performed this comparatively simple operation in twelve cases. It consists of stripping off a short section of the outer covering of the femoral or brachial artery in such a way that a complete circuit of the adventitia, with its network of sympathetic nerves, is removed. It is not sufficient simply to loosen the adventitia from the artery; the whole of the outer covering of the artery must be removed in order that a complete block may be effected in the sympathetic chain. The rationale of this operation depends on the theory that vasomotor-trophic disturbances in the limbs following an injury may be maintained by centrifugal reflexes, conducted by the periarterial network of the sympathetic nerves. These reflexes are supposed to give rise to angiospasm at the site of the injury. These harmful reflexes may be broken either by periarterial sympathectomy or by excision of nerve endings at the site of injury. It has been assumed that the beneficial effects of periarterial sympathectomy are due to the hyperaemia which follows, the harmful influence of an excessive vaso-constrictor action being overcome. In one of the author's cases there was a neurotrophic ulcer below the external malleolus. Sensation in the neighbourhood of this ulcer was diminished, and the foot was colder than its fellow. Four days after the operation there were definite signs of healing, and this was complete within three weeks. Examination of the capillaries near the toe-nails showed definite evidence of improvement in the circulation, and the limb was warmer than before.

The other cases operated on represented a mixed assortment of morbid conditions such as arterio-sclerosis, senile and diabetic gangrene, endarteritis obliterans, and other conditions. The results in many of these cases were disappointing, and it would seem that the sphere of usefulness of this operation is limited. But within strict limits the author thinks the operation may be of value.

### 301. Late Results of Tuberculosis of the Kidneys.

R. BULL (*Norsk Mag. f. Laegevidenskaben*, May, 1923, p. 449) has traced the 24 cases of renal tuberculosis treated at his hospital in the period 1900-21. Twelve pages are devoted to a tabulation of the data collected, and the rule is stressed that while bilateral renal tuberculosis may exist for years and be punctuated by remissions and apparent cures, it seldom, if ever, terminates in complete recovery. In this class there were two cases of particular interest. One of the patients was a woman who, in spite of bilateral renal tuberculosis and no special treatment, improved rapidly and steadily, and was found to be clinically symptom-free at the last examination, five and a half years after discharge from hospital. In the second case there was no doubt about the disease being bilateral, yet the patient still felt perfectly well four and a half years after discharge. He had to micturate only three or four times during the day and never at night. He could still perform most laborious work without the slightest symptoms being provoked. The urine contained no albumin and only a trace of pus. In spite of such cases the author insists on nephrectomy whenever the disease is unilateral.

### 302. Post-typhoid Osteitis of the Radius.

MASSABUAT, GUIBAL, and MARCAN (*Bull. Soc. des Sci. Méd. de Montpellier*, June, 1923, p. 369) record the case of a child, aged 9 years, who gave a history of an attack of typhoid fever two years previously. She was now admitted to hospital with a painful swelling of the right wrist. The swelling, which surrounded the lower end of the radius, had only been present for two months, although the wrist had been painful since her convalescence. The swelling was about the size of a walnut, did not show the signs of acute inflammation, and fluctuation could be elicited without causing pain. Movements at the wrist-joint were free and painless, but pronation and supination were somewhat limited. Radiograms showed a marked thickening of the lower end of the radius surrounding a central cavity in the bone. A Widal reaction was negative, likewise a blood culture gave negative results. At the operation a small collection of pus was found under the periosteum of the radius, whilst an irregular cavity was found in the centre of the bone. This was curetted out and the wound healed satisfactorily. Examination and culture of this pus proved negative. The appearance of lesions of the bone of this nature is not uncommon after typhoid fever; they usually take on a simple form such as an "abscess of the bone" rather than a true osteomyelitis. Surgical treatment is always necessary for these cases.

### 303. The Diagnosis of Carcinomatous Metastases in the Bones.

E. HANHART (*Schweiz. med. Woch.*, June 28th, 1923, p. 619) has investigated the 30 cases of carcinomatous metastases in bones treated in the hospitals of Zürich within only a two-year period. In nearly all these cases the wrong diagnosis had been made by the practitioners sending the patients to hospital, and in 8 cases sciatica had been diagnosed. Spinal syphilis, tabes, a tumour of the cerebrum, meningitis, alcoholic or tuberculous neuritis, coxitis, and arthritis deformans were some of the mistaken diagnoses. The chief reason why these mistakes were made was because the mere possibility of malignant metastases in the bones was not entertained. In as many as eighteen cases the primary tumour was situated in the breast, and the author insists that if there is a history of a tumour of the breast having been removed the practitioner will seldom be wrong if he associates this event with the subsequent development of pain in the bones, bilateral sciatica, deformities, spontaneous fractures, and segmental paralysis. The interval between the development of the primary and the secondary growths may be considerable, and in 3 of the author's cases it was five, nine, and nineteen years respectively. There is no disease which is more painful and distressing, and in several of the author's cases diagnostic mistakes and ill chosen treatment had added to the patients' misery. A combination of the most complicated and technical diagnostic methods may yield less information than a careful clinical examination by a practitioner who remembers that secondary carcinomatous growths in the bones are quite common.

statistics to-day, I decided that it would be more expedient to leave figures alone and to treat the subject from a clinical point of view, and in my remarks I shall endeavour to deal especially with points having a direct bearing on some of the reports kindly sent to me in private correspondence.

During the past fifteen years so much progress has been made in the science and art of anaesthesia, especially in the direction of safety, that we may well feel encouraged to make further efforts in this matter, and the chance of success may be greatly enhanced by the keen interest which the general practitioner is taking in the specialty.

It seems reasonable to hope that co-operation amongst members of the profession may, before long, result in a reduction of the total number of these fatalities reported annually by the Registrar-General. For some years this figure has remained almost stationary, although there has been an enormous increase in the number and severity of operations performed annually, and in spite of the fact that old age or feebleness is not allowed to stand in the surgeon's way to the same extent as formerly. In fact, the surgical burdens, if I may use the phrase, which patients are nowadays expected to bear are often so heavy that without improved anaesthesia the mortality would have risen much higher than is the case. If we try to determine in what direction further improvement is most likely to occur, we are handicapped by the lack of detail in the reports of coroners' inquests, and in the usual statistical tables, but with the help of practical knowledge we may, I think, arrive at many useful conclusions.

We may classify anaesthetic deaths according to the time at which they occur—that is, whether before, during, or after operation.

We have, then, in the first group, fatalities caused by the anaesthetic without the complication of other factors such as shock or haemorrhage. A large majority of these cases are associated with the use of chloroform for inducing anaesthesia, and have practically disappeared in those clinics which have adopted the principle of avoiding this drug entirely during induction, or at any rate during the stage of excitement. It seems only reasonable to expect that before very long all administrators will follow this routine and thus rob chloroform of something like 50 per cent. of its immediate danger. The method of using chloroform at the very commencement, and changing to ether before the onset of struggling, imposes certain responsibilities upon the administrator. In the first place, he must be prepared for the very insidious onset of this anaesthesia, which may be indicated only by a slight depression in the respiratory rhythm, or volume, and may be easily overlooked amidst noisy or distracting surroundings. In the second place, it may require considerable determination on his part to resist the temptation to use a little chloroform in order to overcome troublesome spasms, and this temptation is apt to be increased when there is need to hurry. Induction by chloroform is apt to be followed very quickly by a stage of marked muscular relaxation, during which moving the patient from one table to another may give rise—and often has given rise—to fatal syncope.

In consequence of these difficulties we must regard the practice of inducing with chloroform as too dangerous for routine work. In looking for an alternative method of commencing the induction we are apt to forget that ether alone is not intolerable when administered sufficiently slowly, and that ethyl chloride and nitrous oxide are available not only in closed methods; they can be used with the open mask, ethyl chloride being sprayed on, or nitrous oxide being run underneath it.

Our second group of cases—namely, those occurring during the course of operation—is difficult to analyse, consisting of a veritable fabric of factors and a riddle of responsibilities. Fortunately the co-operation between surgeons and anaesthetists is well established and shows signs of vigorous growth, with the result that the patient's power of resistance is seldom overtaxed nowadays. There is always some difficulty in determining the proportion of blame due respectively to surgeon and to anaesthetist. Take, for example, an instance where shock develops

after prolonged and continuous manipulation of intestines, or traction on the mesentery; it is probably true that if the manipulations had been interrupted by pauses for "rest," the shock might have been avoided, but the blame for this should be laid at the door of the anaesthetist, provided he has omitted to warn the surgeon that a rest was indicated. Take, as another example, an instance where too tight packing of the abdomen during operation has led to shock. Some justification, that such excessive packing was rendered necessary by insupportable relaxation, but the anaesthetist may feel tempted to retort that relaxation could have been procured locally by the injection of morocain more safely than by a further saturation of the patient with the toxic anaesthetic. This question of combining local with general anaesthesia is one which needs investigating, and calls for close co-operation between workers, a complete understanding on this point might, on occasion, avert disaster.

When a patient, already moribund from illness or disease, dies during operation, it is misleading to attribute death to anaesthesia; it is due to natural causes or perhaps to surgery.

While it is difficult to lay the blame for accidents arising in the second group of cases, it is well-nigh impossible to do so in connexion with the third category, which comprises deaths resulting from sequelae. It is important that the anaesthetist should be notified of any upward symptom, which could possibly be attributed to his administrations, otherwise he will have no reason to expect the surgeon to value his lesson; nor is it his duty to expect the surgeon to view these complications from the anaesthetist's standpoint. For example, collapse and severe fall of blood pressure will suggest to the former that his operation was too exhausting, whereas to the latter it will probably indicate that saline ought to have been administered more freely, that more frequent halts should have been called during the operation, or that some form of local anaesthesia might have been employed in conjunction with the general anaesthetic. Again, in the event of chest trouble developing after operation, the surgeon is apt to blame ether when possibly some other factor, such as tight bandaging or strapping restricting the movements of respiration, has been the real cause.

There are many instances of this type which may occur to you, where the factors concerned are so numerous as to make it hard to say in what direction our technique requires revision. It is when these complications are met with that the surgeon may, with the best of intentions, demand some change of method which will lessen risk in one direction but which may increase it in another. I hope we shall soon see every case of sequelae after the subject of consultation between surgeon and anaesthetist. The prevalence of deaths due to chest complications may be increased by our natural inclination to avoid, at all costs, the tragedy of a death on the table; the method which is the safest during operation may be the most dangerous in the long run. Take, for instance, the case of an elderly patient with bronchitis on whom herniotomy is to be performed; he could probably be brought through safely with closed ether, but he would run a grave risk of an acute exacerbation of his lung condition. It is probably still in avoiding post-operative fatalities than by his success at the time of operation.

It is evident, then, that the course of progress is not quite so free from "snags" as it may appear to be at first sight, and that some careful navigation is necessary at the point where we and ourselves to-day. As one of the most difficult "snags" we have to negotiate I may mention education. The post-graduate cannot learn much from occasional lectures, and the student is required to devote only a small amount of practical study to the subject of anaesthetics; this, however, is an advance on the conditions obtaining twenty years ago, when it was not uncommon for a newly qualified man with no previous experience to be called upon to give the anaesthetics for the day in his hospital with no one to guide him but the operating surgeon.

**310. Treatment of Febrile Abortions.**

DUBROWITSOH (*Zent. für Gyn.*, August 18th, 1923, p. 1327) gives statistics of 445 cases of febrile abortions treated in the maternity clinic at Giessen during the years 1912-23. Of these, 265 cases were actively treated when the temperature was raised, 89 cases were treated absolutely conservatively, and 91 cases had expectant treatment, the uterus being cleared out several days after the fall of the temperature. It was found that the mortality was greatest in the cases that had received active treatment and the morbidity was least in the cases treated expectantly, whereas the morbidity was much the highest in the cases treated purely by conservative methods. The author comes to the following conclusions, derived from his series of cases: (1) Active treatment of febrile abortions is not so satisfactory as the expectant treatment. (2) There seems to be no connexion between the mortality figures and the height of the temperature at the time of delivery. (3) The manner of clearing out the uterus, whether by the finger, blunt curette, or ordinary curette, hardly influences the mortality at all. (4) Abortions which have had to be cleared out are more unfavourable than those that come away without interference. (5) The mortality is highest in criminal abortions. (6) The higher the temperature rises the more likely is morbidity to ensue. (7) The greater the interval between the fall of temperature and the clearing out of the uterus the less the morbidity. (8) Morbidity is least in natural abortions, higher in examined cases and in those operated upon, and highest in criminal abortions.

**311. Syphilis of the Corpus Uteri.**

ACCORDING to B. PORTIS (*Surg., Gynecol., and Obstet.*, July, 1923, p. 37), syphilis of the body of the uterus is rare, and many of the non-gummatous lesions which have been reported rest on insufficient evidence. Among the tertiary lesions which have been described are (1) syphilitic arteritis, which is associated clinically with increased haemorrhage rather than with modification of the shape or size of the uterus; (2) sclerosis of the myometrium, which may be associated with some hypertrophy; (3) atrophy of both the myometrium and endometrium, so that the uterus becomes very small and hard; (4) gummata which are frequently associated with much hyperplasia and sclerosis. A case is reported by the author in which the *Treponema pallidum* was demonstrated between the muscle bundles of the corpus uteri, and in which affection of the uterus occurred at a comparatively early stage, as shown both by the cellular character of the inflammatory reaction and by the development of typical secondary cutaneous syphilides seven weeks after the onset of the first local symptoms. The patient, who was 38 years old and had had eleven children and no miscarriages, complained of irregular bleeding; the cervix was indurated, thickened, and ulcerated behind. Both broad ligaments were somewhat indurated and contained small irregular palpable masses; a clinical diagnosis of carcinoma cervicis having been made panhysterectomy was done. The treponema was found not only in the body of the uterus but also throughout the cervix, which had probably been the site of the primary lesion, and in a corpus luteum and the surrounding ovarian stroma.

**Pathology.****312. Failure of Peptone to Protect against Anaphylactic Shock.**

CONSIDERABLE success has been claimed in recent years for the use of peptone in allergic conditions such as urticaria and bronchial asthma. To test its value N. P. LARSEN, A. V. R. HAIGH, H. L. ALEXANDER, and R. PADDOCK (*Journ. of Immunology*, September, 1923, p. 409) performed several experiments on guinea-pigs which had been previously sensitized to egg white. One c.c.m. of a 1 in 2 emulsion of egg-white was injected intracardially into a series of 25 guinea-pigs; twelve days later 0.5 c.c.m. of a 5 per cent. suspension of peptone in saline was injected in the same manner, followed thirty minutes after by 0.2 c.c.m. of the egg-white emulsion. The results showed that the percentage of deaths amongst the animals was higher than that occurring in 16 control animals which had received no protective dose of peptone. In another series five doses of peptone were administered in between the sensitizing and the dechaining doses of egg-white; the results here corresponded to those obtained in the control experiment. They then worked out the effect produced by adding peptone to a bath in which strips of sensitized guinea-pigs' uteri were suspended, and found that not until the concentration of the peptone in the bath reached a figure of about 1 in 500 was the contraction caused by the subsequent addition of egg-white prevented.

Following up this work they treated nine patients suffering from bronchial asthma by intravenous injections of peptone; the results obtained did not impress them favourably.

**313. Experimental Investigation of the Blood and Bile Channels of the Liver.**

H. N. SEGALL (*Surg., Gyn., and Obstet.*, August, 1923, p. 152) describes an investigation he has carried out on the normal and abnormal distribution of the blood and bile channels in the liver. The technique adopted was that described by Gross, which consists in injecting an emulsion of barium sulphate in gelatin and making x-ray pictures of the injected vascular tree. A study of 55 livers was made, and it was shown that the intrahepatic branches of the hepatic artery are quite straight in the earlier decades of life, but become more tortuous with advancing age. The subcapsular arterial anastomoses and those in the tissues of the portal vein form the collateral circulation between the right and left branches of the hepatic artery. The course of collateral circulation between a patent and obstructed branch of the hepatic artery is from the collateral vessels into their larger parent vessels, thence to the main branch to the point of obstruction, and finally to the ramifications of the blocked artery. The hepatic veins form three groups. The central group receives a few small radicals from the gall bladder, the venous blood of which is mainly drained by the vena cystica. Arterial blood is absolutely essential to the nutrition of the liver substance. Complete obstruction of either branch of the hepatic artery does not affect the liver substance owing to the abundant anastomoses which afford efficient collateral circulation. Infarcts of the liver follow obliteration of those arteries which terminate without sending branches to the subcapsular anastomoses, and are therefore proper end arteries. It appears that in tracing the effect of ligation at various points along the hepatic artery, the nearer the ligation to the point of bifurcation the greater will be the danger of necrosis. The danger of necrosis in human subjects diminishes in ligation of single branches distal to the bifurcation.

**314. The Adrenaline Test in Diseases of the Thyroid Gland.**

H. VAQUEZ and C. DIMITRACOFF (*Arch. des Mal. du Cœur, des Vaisseaux et du Sang*, June, 1923, p. 414) refer to the excitant action of adrenaline on the sympathetic system—a hypodermic injection of 1 mg. in “sympathicotonic” cases produces tachycardia, tremors, sensations of cold or heat, emotional outbursts, rise of blood pressure, and sometimes glycosuria. Goatsch (Baltimore) has used adrenaline as a test for hyperthyroidism, and has shown that patients suffering from exophthalmic goitre react strongly; he concludes that this hypersensibility is proportional to the degree of hyperthyroidism. Others have confirmed his observations. Bloch states that the test is also positive in pregnancy, diabetes mellitus, and acute rheumatism. The authors state that while radiotherapy gives most satisfactory results in exophthalmic goitre there has hitherto been no satisfactory method of selecting cases, nor of testing the utility or the duration of treatment. Slowing of the pulse is insufficient for the purpose. Numerous records of the appearance of myxoedema have shown that radiotherapy has been carried too far. In nervous instability a negative Goetsch test is important—the treatment may do actual harm. The authors have used this test in 15 cases and describe their technique. They take the pulse and blood pressure (using a sphygmomanometer and the auscultatory method) before and every two or four minutes after the intramuscular adrenaline injection; the readings are charted and any subjective disturbances noted. The test is: (a) *Positive* when at least three phenomena are observed—(1) delayed tachycardia (that is, appearing about thirty minutes after injection); (2) rise of systolic blood pressure; (3) definite subjective disturbances—pallor, vertigo, palpitation, etc. (b) *Partially positive* when there is only slight rise of blood pressure and tachycardia—alone, or with more or less marked functional disturbance—appears. (c) *Negative* when there is no appreciable result. The authors classify their cases in three groups: Group 1, those with definite symptoms and positive reaction, indicating treatment; a subsequent test shows progress made and the period at which treatment should cease. Group 2, those cured or improved, but possibly showing, after an interval, some abnormal signs. The test indicates the degree of hyperthyroidism present and the need or otherwise for further treatment. Group 3, patients diagnosed clinically, but a negative test shows that radiotherapy would be useless or dangerous. Six typical charts are given with full details of each case. The authors conclude that the test is a true biological reaction which proves the existence or non-existence of hyperthyroidism; and is a valuable aid to prognosis.

two fingers being easily inserted into the rectum without causing any discomfort. There had been marked prolapse, and this was only slightly improved. His general condition was poor.

Perhaps the most striking case was one where the man had suffered for fifteen years, and it was with some difficulty that he was persuaded to submit to out-patient treatment. For some years he had been forced to wear a support to prevent prolapse of the rectum whilst walking. The mucous membrane was seen to be very markedly prolapsed and several piles were present, the anterior pile being the size of a walnut and the left lateral the size of a very large Brazil nut. The latter after two injections was completely thrombosed and the anterior after three injections. Prolapse soon disappeared, the anal orifice became normal, the sphincters regained their tone, and no stricture of the canal had developed.

Before subjecting a patient to this treatment he should be as thoroughly examined as if a major operation were to be performed. I would strongly insist on this, as the only death with which I am acquainted occurred in a case of advanced Bright's disease. Too much carbolic should not be injected—2 to 5 minims of the mixture is sufficient to inject into a pile at one time—and not more than three amounts of carbolic are injected carbuncula may result. Bright's disease, diabetes, pernicious anaemia, advanced cardiac disease, hemiplegia, and epilepsy are all contraindications.

The advantages of the method are that it is almost painless—some nervous patients (especially women) complain of pain for some time afterwards, but this is very rarely severe; no anaesthetic is required; and the treatment can be carried through from beginning to end without the patient being incapacitated or his daily routine interfered with. Since completing this series, I have tried the effect of injecting 50 per cent. sodium salicylate into piles. The results of the few cases (40) thus treated are as good as those treated with carbolic acid, but the pain immediately after injection is more severe and lasts longer.

## HAEMORRHOIDS IN ASSOCIATION WITH TUBERCULOUS FOCI IN THE CHOROID.

J. D. CUMMINS, M.D., B.Ch., R.U.I.,  
ASSISTANT SURGEON, ROYAL VICTORIA EYE AND EAR HOSPITAL, DUBLIN.

It may be said that the diagnosis of tuberculous inflammation of the middle coat of the eye, assuredly a secondary infection, is a matter of more or less clinical probability. The family history and the personal history of the patient, together with the finding of a tuberculous lesion elsewhere and the exclusion of *Spirrochaeta pallida* infection, form, as a rule, the basis of one's etiological belief. There is also that fallible but often trustworthy factor, clinical investigation of clinicians. A diagnosis help that may have unfavourable consequences in this relation is the hypodermic injection of Koch's old tuberculin. Its value is definite only if it be followed by the occurrence of irritation or an increase of irritation in the affected eye. But one cannot foresee how much irritation may arise, and it has happened that such an aggravation of the inflammation has provoked that neither patient nor oculist was pleased with the mode of confirming the diagnosis.

### CASE I.

Miss T., aged 25, had noticed, one week before visiting me, that the left eye was blind. She had lighted a candle in a dark room and upon turning sideways towards the light, thought it had gone out. She then faced the lighted candle and, by closing each eye in turn, found that the left one was blind. When I examined this eye its pupil was inactive to direct illumination, there was a floating opacity in the vitreous humour, and the disc, which was scarcely recognizable, seemed to be enveloped in a bulky oedema with a

streak of haemorrhage on its surface. The floating opacity situated in the centre of the vitreous and was so delimited as to allow of the red reflex being clearly seen all round it. The blood had been poured out into Cloquet's canal. Towards the nasal side of the disc was seen a patch of choroidal atrophy bordered by a line of dark pigment. The eye was blind. One month later I noted "floating opacities" in the vitreous; pale disc indistinctly outlined; periphery of disc slightly prominent; arteries small. After five months the disc had the ill-defined appearance, pale colour, and smudged edge of secondarily atrophic. Immediately following the lower border of the disc and spoiling its regular contour was a pale area about one-fourth of the disc's diameter in size. The right eye was normal.

Miss T.'s brother, aged 27, asked me to look at his right eye, which was not as good as the left. Below the right macular region were a sharply outlined, brilliantly white patch (almost as large as the disc) of choroidal atrophy and a tiny ill-defined pale nodule alongside it. The visual acuity of this eye was 6/18; the other eye was normal.

Both brother and sister had always enjoyed good health. Miss T. declared herself to be somewhat run down, in consequence, she believed, of her nursing duties during her mother's last illness, which had terminated three months previously from heart failure. Their mother, over 70 at the time of her death, had suffered for years from a bronchial affection, which was said to be of a non-tuberculous nature. A sister of theirs, a child of 13, died of pulmonary tuberculosis.

### CASE II.

E. B., a robust young woman of 24, noticed, a few days before coming to hospital, that the vision of the right eye had become greatly impaired. With this eye only shadows could be seen. The vitreous contained a large felt-like mass, which effectively obscured all details of the fundus. It was thought that a dimly seen glistening streak might be a tear in the retina. The other eye was normal. A general examination failed to reveal anything amiss. A differential blood count presented the normal picture. Keen avoidance of stooping, and 5 grains of calcium lactate daily made up the treatment.

Three years later the patient returned to hospital on account of a simple phlyctenular conjunctivitis.

After her last visit she had remained in bed for one year. The vision of the right eye was 6/12, and of the left one 6/12 (partly). Far forwards in the vitreous chambers were seen floating knots and threads. Each fundus exhibited at the periphery, the albino appearance seen after atrophy of the retinal pigment layer. There was in the right eye a patch of choroidal atrophy, and in the left one a raised focus at the junction of the lower and nasal borders of the disc. Engorged vessels were arched over the prominence.

Very often one sees in chronic tuberculous choroiditis foci in different stages of evolution. Some of the foci will have become atrophic patches, others will be recent, showing ill-defined edges and raised forms. In the first case some support was given to the diagnosis of tuberculosis by the family history and the examination of the brother's eye. Both patients gave a negative Wassermann reaction. The phlyctenular conjunctivitis of the second case was not, in a pathological sense, out of place. But perhaps it is best to say that the opinion of the nature of the cases is the result of cumulative clinical impressions.

## APPENDICITIS AND INTUSSUSCEPTION IN A DOG. BY JOHN D. MACCOLL, F.R.C.S., EDIN.

A letter, aged 87 weeks, when seen on November 26th, 1922, was in a state of extreme emaciation with a poor appetite, and hardly any of the likeness of a puppy. The bowels, which were at first relaxed, later became constipated. Castor oil caused vomiting and loose motions but did not clear the intestine. There was no abdominal distension nor definite evidence of pain on manipulation. On November 15th and 16th hard masses were felt towards the pelvis. On November 17th an oedema appeared at a distance of 12 inches from the small gut. The peritoneal surfaces at the distal four inches of the small gut.

and allowing the surgeon at any moment to estimate the actual state of affairs, its special suitability for use in the aged, its usefulness in cases where any increased turgescence of the respiratory tract is inadmissible, and its almost absolute safety when given through a laryngotomy or tracheotomy opening.

On account of its immediate dangers chloroform is absolutely inadmissible in infants and children in all circumstances; it should never be used for trivial operations, and what may be called casual anaesthetics; and it should not be used for robust and young or middle-aged adults unless called for by some very special indication.

On account of its liability to produce progressive metabolic disturbance of the delayed poisoning type, chloroform should never be used in young people suffering from acute or chronic infections, in patients suffering from malnutrition or starvation, or in diabetics.

On account of its relatively shallow anaesthesia and the liability of post-operative vomiting, when it occurs, to be persistent, chloroform is not usually admissible in serious abdominal work.

In my own practice chloroform is used in all mouth, jaw, larynx, and pharynx cases, almost invariably in combination with laryngotomy or tracheotomy. I have never seen the least cause for anxiety in a series of many hundreds of cases of this type after the windpipe has been opened, though I have known an unaccustomed anaesthetist to be a good deal disturbed by the periodic respiration with long apnoeic pauses that usually sets in in elderly patients after tracheal breathing has been established. Chloroform is also used for a large number of the brain and spine operations and for the radical operation for breast cancer. This last indication deserves perhaps a word of comment. The exaggerated breathing and excited circulation of ether anaesthesia make it especially ill suited for an operation which strips so large an area of the chest wall and divides so many veins that pierce it; moreover, the same effects of ether, while they add to the shock, disguise its onset. It is because chloroform so precisely avoids all these disadvantages that it seems decidedly to be preferred to ether in this operation.

Nitrous oxide is singular among the anaesthetics of this group in being incapable of producing an anaesthesia comparable in profundity with that of ether or chloroform. In my experience it is only in delicate or enfeebled patients that gas can be relied upon by itself to produce a steady and adequate anaesthesia. It will usually be necessary to supplement it by the local or regional anaesthetization of the part to be operated upon. The efficiency of the method is increased by the use of narcotics. The procedure in outline is, in order: (1) a hypodermic injection of morphine hourly for the three hours preceding the operation; (2) nitrous oxide administration; (3) regional or local anaesthetic injection. Any but the most extensive abdominal operations can usually in suitable cases be done under this anaesthetic régime with complete success. The addition of small amounts of ether vapour to the inhaled gas, as is well known, extends the applicability of the method to many patients in whom it would otherwise be impossible. This addition, however, brings with it the risk of sacrificing the chief advantage of the procedure by inducing post-operative vomiting, so that an effort to avoid it is always made in my practice, even at the cost of some inconvenience to the surgeon.

#### *The Regional Methods.*

Spinal anaesthesia in the hands of the expert has no longer the disadvantage of any serious degree of uncertainty. Its usefulness is limited anatomically and physiologically.

Anatomical limitation brings it about that any operation at all prolonged cannot be extended much above the umbilicus; physiological limitations make it necessary to confine the method to patients in whom the circulatory system is in reasonably good condition and capable of reaction. Spinal anaesthesia is not, therefore, an anaesthetic suitable for enfeebled patients or for those with acute and serious abdominal conditions. It is a grave mistake to suppose that it is a possible substitute for inhalation methods when these are thought to be inadmissible on account of cardiac or vascular diseases. Its special usefulness is for operations on the lower limbs, perineum, pelvis, and lower abdomen where shock is greatly to be feared (amputation high in the lower limb); where metabolic complications are to be avoided (diabetic gangrene); and where full abdominal relaxation is essential (large abdominal herniae in fat subjects). It should generally be preceded by narcotic

drugs and may often be usefully combined with the use of nitrous oxide. The free use of narcotics seems to do away with the risk of vomiting during the operation, and perhaps to diminish the incidence of headache afterwards.

Sacral anaesthesia has a small but very definite range of usefulness in limited operations on the perineum. For pile operations it gives just the anaesthesia that is needed, together with complete relaxation of the sphincter. It should, of course, be combined with narcotics. In some cases the conformation of the sacrum prevents it being carried out, but this condition can always be determined beforehand.

Nerve trunk anaesthesia is more commonly known as regional anaesthesia. It is given this name here to distinguish it from methods that are regional in a wider sense.

All local anaesthetics do and should contain a regional element, but there are a few cases in which the definite blocking of nerve trunks has shown itself to be a trustworthy and thoroughly practical method. These special cases of nerve blocking are rendered possible by anatomical conditions. Two are in common and satisfactory use—the blocking of the intercostal nerves for operations upon the chest and abdomen, and the blocking of the brachial plexus above the clavicle for operations on the upper limb. Both procedures require a certain expertness, but there can be no doubt that they should be in regular use in suitable cases. The usual combination with narcotics, and possibly with nitrous oxide, should, of course, always be considered.

#### *The Local Method—Infiltration Anaesthesia.*

Next to ether anaesthesia this is undoubtedly the method which is capable of the widest application. It is tedious to induce, and in its larger uses demands wide experience and expert knowledge. It may be regarded as having two more or less distinct ranges of usefulness: (1) in conditions where it is obviously indicated by the anatomical situation and nature of the operation, as in all superficial and definitely limited dissections, in radical cure of hernia, especially inguinal and umbilical, and in excisions of the testicle; (2) as a special procedure where other methods are urgently contraindicated it may be applied by the expert to almost any of the operations of surgery, except where diffuse infective conditions have to be dealt with. I personally do not make use of it as a routine for cerebral operations, for thyroid operations, or for extensive dissections of the neck, but it is well established as a method that is applicable to these and many other equally extensive procedures.

I do not propose to say anything about technique, but in all the wider applications of local infiltration the preliminary use of narcotics, the injection of an abundance of solution, and the giving it full time to act, are the principal factors in success.

We have now reviewed the methods which may be regarded at the present time as well established, each in its own special field of usefulness. I have mentioned no method which I have not learnt in my own experience to be, in appropriate circumstances, trustworthy and thoroughly practical. They represent the facilities which the surgeon and the patient are justified in demanding from the expert anaesthetist. I have tried to indicate in a general way the considerations which should guide us in the choice of an anaesthetic in a given case. There are a few rules that must be regarded as absolute, at any rate for the time; but on the whole it must be recognized that we are very far from absolute standardization. I confess that I am not very sympathetic with the ideal of complete standardization in surgical technique. While we have to deal with factors so incorrigibly variable as disease on the one hand, and the human mind and body on the other, concentrated and independent thought will always be necessary for the proper achievement of every surgical act.

II.—**SIR WILLIAM I. DE C. WHEELER,**  
President, Royal College of Surgeons in Ireland.

WHEN I was asked to take part in the opening of the discussion on "Anaesthetics from the surgeon's point of view," I was rather at a loss from what angle to view the subject. The task would be easy if the title had been slightly altered, and we were asked to talk about "Anaesthetics from the surgeon's point of view." I know of no better exercise in self-restraint than the performance of a difficult abdominal

# Memoranda : MEDICAL, SURGICAL, OBSTETRICAL.

## AMYL NITRITE POISONING.

A few weeks ago a retired medical man asked me to see him on account of anginal pain in the chest coming on at night. The blood pressure was 145 mm., the heart sounds rather moderate, and the abdomen distended with flatulence. About ten that night he had an attack of pain, for which a medical friend gave him a small hypodermic injection of morphine, and left him quite comfortable. The pain returned about 1.50 a.m. Half an hour later his housekeeper telephoned for me. When seen he was in a state of extreme collapse, hardly able to speak, very pale, with a weak pulse of 120. Five amyl nitrite capsules were lying on his bed. Having been inhaled in less than an hour. His blood pressure was only 76 mm. Camphor by hypodermic injection, brandy, and hot bottles more or less revived him. Next day he had a very irritating spasmodic cough with rusty sputum. The respirations were 40, the temperature 56.4°, pulse 108, blood pressure 80 mm. His chest from the third space downwards was full of fine soft crepitations; there was no tubular breathing anywhere. His tongue was dry increased dyspnoea. There was also watery diarrhoea. The spirations remained at 40, and any movement caused in days the sputum was deeply blood stained and frothy; re- quarters of an inch came off it on the fifth day. For nine it had been burnt, and a slough about one inch by three in and brown, as also was his soft palate, which looked as if space downwards was full of fine soft crepitations; there was no tubular breathing anywhere. His tongue was dry increased dyspnoea. There was also watery diarrhoea. The spirations remained at 40, and any movement caused in days the sputum was deeply blood stained and frothy; re- up for an hour. There was no anginal pain all through, and the blood pressure was still only 90 mm. on the twenty-first day.

The case rather resembled chlorine gas poisoning; apparently the nitrous acid in the amyl nitrite acted as a severe irritant to the lungs. Whether any of the dyspnoea was due to the formation of methaemoglobin in the blood was not investigated. There were no convulsions as described in amyl nitrite poisoning of animals.

WALTER BROADBENT, M.D., F.R.C.P., Physician, Royal Sussex County Hospital.

## CHOLELITHIASIS WITH SITES INVERSES.

The following case may prove of interest :  
Mrs. J., aged 43, was admitted on August 21st to the Manchester Royal Infirmary complaining of pain in the left hypochondrium and under the left breast; the pain was also described as going round to the back and into the left shoulder. The patient was markedly jaundiced, the urine contained bile, and the stools were clay-coloured. The description and distribution of the pain were typically those of an attack of gall-stone colic except for the fact that it was on the left instead of on the right side, and the patient gave a history of having had eight similar attacks during the previous three months, each having been followed by jaundice. On examination, an indefinite tender mass was palpable at the tip of the ninth left costal cartilage. Murphy's sign was absent, and there was no examination confirmed the presence of dextrocardia. In view of this, and the distribution of the pain and tenderness, a condition of complete transposition of viscera was suspected. The patient said that she was, and always had been, right-handed.

On August 27th Mr. A. H. Burgess explored the abdomen through a left upper rectus incision: all the viscera were completely transposed. The gall bladder and common bile duct, which was much dilated, contained several large stones, and cholecystectomy and cholecystostomy were performed.

## Reports of Societies.

### COMPARATIVE MEDICINE.

The first meeting of the new Section of Comparative Medicine of the Royal Society of Medicine was held under happy auspices. A large audience gathered in the Society's rooms on October 24th to celebrate a day which the President, Sir Clifford Allbutt, described as a festival rewarding long and patient effort. The acclamation with which his eloquent address was received indicated that those who were present recognized what an important share he has taken in the enlightenment of opinion which has led to the inauguration of this Section.

Investigate and impracticable barriers of convention, devised by medieval perverters, have, he declared, split up medicine into fractions, divorcing medicine from surgery and separating diseases of animals and plants from those of mankind. The folly of many of these divisions is apparent, but their eradication is a difficult operation. One such barrier has been broken down by the co-operation of medical and veterinary scientists, thereby acknowledging the unity of medicine as a biological study.

Medicine has much to gain from the comparative method of study, a method which has proved indispensable to the progress of anatomy, anthropology, and embryology. Pathologists have already made some use of the comparative method of study, and by their researches into the properties of cells and nature of infections have gathered in some knowledge. The comparative method is necessary in medicine in order "to shed cross lights reciprocally from the pathology of one kind of living thing upon another." It will also have a utilitarian purpose, to study the diseases common to man and animals and the manner in which these diseases may be carried by animals to man, to investigate the peculiar natural immunity of certain animals to certain diseases, and the defensive processes of animals and plants. But, as Sir Clifford Allbutt pointed out in a letter to the *Times* in 1896, the attention of those who would study the comparative medicine should be concentrated on the pursuit of larger and more distinguished researches, on "a pathological biology which hereafter shall give us not only a control of several diseases, but an insight into large and fertile principles, forces and controls over wide fields of nosology, interpretations of the various communities and of the manifold kinds of disease in all living things—

## PRELIMINARY NOTE ON THE HISTIOLOGY OF A MYELOMA.

A TUMOUR from the radius of a child was examined, and the following observations made. We hope to publish details at an early date.

1. The appearance and structure of the numerous giant cells present suggest that they are osteoclasts.

2. In our opinion the giant cells give rise to the spindle cells of the tumour.

3. The fibroblasts appear to be derived at a later stage from the spindle cells.

4. In several of the giant cells we found a stainable body, quite unlike the giant cell nuclei in appearance, which may very probably be responsible for the abnormal activity of the giant cells. There is some evidence in favour of the view that the stainable body is a definite parasite—probably a protozoan—which is not confined to the giant cells.

D. J. HARRIS.  
T. H. BERNARD.  
Cardiff.

Manchester.  
E. S. FRISCHMANN, M.B., CH.B.  
It is an interesting point that the patient's eldest son, aged 12 years, is a typical example of Fröhlich's type of infantilism, being about five feet in height, exceedingly fat, mentally slow, and with undeveloped genitalia. In all other respects the family history is quite normal, the two other children being perfectly healthy.

performed. The patient made a rapid and uneventful recovery.

One of the last cases under my care was one of the Ministers of the Irish Government, who was wounded in the back by a bullet. The spinal column was hit, and the bullet was deflected so that it came to lie above the right kidney in the region of the diaphragm. After the operation for extraction, fine crepitations could be heard at the base of both lungs; there was expectoration of rusty sputum, the temperature rose, and for a few days the condition of the patient gave rise to anxiety, but with the healing of the wound and gradual relaxation of the muscles the pulmonary complications, as is usual, disappeared.

I would, therefore, suggest that crepitations at the base of the lungs may be a sign in favour of an acute upper abdomen, and not against; that frequently crepitations are heard after high abdominal operations owing to rigidity of the diaphragm and recti muscles; that the tightening of the abdomen after the closure of a large ventral hernia may be followed by fatal pulmonary oedema; and that the condition—often referred to as "chestiness" by the students and house-surgeons—after operations has nothing whatever to do with the anaesthetic.

3. In conclusion, I would like to refer to the great advantage of using a local anaesthetic with or without general anaesthesia. Nearly twenty years ago I learned my first lesson in this method from the late Theodor Kocher, and I have seen your distinguished President adopt the method in numerous cases.

Whatever the operation, the subcutaneous tissues are infiltrated first and the deeper tissues afterwards, before the incision is made, with a 1/2 or 1 per cent. novocain and adrenaline solution, thus blocking off as far as possible the operation area from connexion with the cerebro-spinal centres. Complete relaxation of muscles is obtained, and the anaesthetic solution, finding its way along intermuscular and interfascial paths, renders the various layers to be divided plain and distinct. Bleeding is reduced to a minimum, and in the blanched area nerves and blood vessels stand out in a manner only seen in the dissecting room. I think there is no doubt whatever that the shock of an operation is considerably decreased, and the short time and labour involved in the infiltration of a local anaesthetic is repaid a hundredfold.

For some time abdominal and other major cases were operated upon with local anaesthesia alone, but the strain on the surgeon is greater, and if, in abdominal cases, any drag is put upon the mesentery the patient complains of severe pain in the back, and occasionally unexpected difficulties are encountered and a general anaesthetic becomes necessary. To pass from a local anaesthetic to a general anaesthetic in the middle of an operation for obvious reasons is to be avoided. It is better to commence by a combination of both, unless in those cases which are almost certain to be straightforward and uncomplicated. Local anaesthesia for tracheotomy is ideal, and it is a great advantage to inject 10 minims of 2½ per cent. cocaine solution into the trachea before opening to obtain tranquil tracheotomy, as recommended by StClair Thomson. There is no reflex cough, no danger of aspiration of blood, and no disturbance rendering difficult the introduction of the tube.

A general anaesthetic need never be used in cases of varicocele, bunions, hammer-toes, the straight appendix operation, and so forth. In abdominal operations the parietal peritoneum becomes absolutely lax and insensitive if the overlying subcutaneous tissues and muscles are infiltrated. Provided there is no pulling on the mesentery, there is no pain, but any tension transmitted to the posterior peritoneum produces the pain in the back, seen in all conditions which directly or indirectly involve the posterior parietal peritoneum, such as gall-bladder diseases, posterior gastric ulcer, and abdominal aneurysm.

Time does not permit a reference to the dangers of chloroform, but it is difficult to understand on what method of reasoning it is still administered for the removal of tonsils, having regard to the danger of status lymphaticus, or in prolonged bone operations in children, with the ever-present danger of acidosis, or in cases of the septic abdomen, for in the latter case the extra burden put upon the liver in eliminating the toxins of chloroform may prove fatal.

The preparation of patients for an anaesthetic requires thought. Crile attributes much of his success to the painstaking preparation of cases of hyperthyroidism before thyroidectomy. Suffice it to say that preliminary purgation is unsound; brisk purgation before and sips of water after is a sure way of adding to discomfort and, to some extent, to the dangers of operation. Fluid should be given in unrestricted quantities to within an hour of operation, and as soon after as possible. Stomach cases are no exception to this rule.

Troubles for which anaesthetics are often blamed are conspicuous by their absence if there is a proper preparation before operation, and not too many restrictions for the few days following. The sisters in Mercer's Hospital in charge of the wards have the following written instructions in connexion with the patients under my care:

#### *Preparation before Operation.*

1. Twenty grains of bicarbonate of soda every four hours for two or three days if necessary, until urine is alkaline.
2. Large quantities of water by the mouth, or saline by rectum, for the ten or twelve hours preceding operation.
3. In anxious cases, or in children about to undergo bone operations, glucose to be given if possible for two or three days before operation.
4. No enema on morning of operation.
5. No laxatives to cause purging in patients preparing for operations. Simple laxatives, as in non-operative cases, are alone necessary a day or two before.
6. Special instructions to be given in cases of intestinal cancer.

#### *Patients after Operation.*

1. Unless restricted from some special reason, such as fracture of bones, etc., the patient may move as much as he likes in bed from the first after operation.
2. The patient may sit up out of bed on the second or third day after ordinary operations, provided they are not drainage cases and there is no fever.
3. The freedom of the room to be given after four days; a bath after seven days, and out for walks or drives not later than the tenth day.

#### DISCUSSION.

Dr. A. L. FLEMING (Bristol) said that he felt a considerable sense of responsibility in taking part in the discussion because it dealt with a very important feature in the progress of the specialty of anaesthetics; and he was relieved to find that Mr. Trotter had laid stress upon the necessity for co-operation between surgeon and anaesthetist, so essential in modern surgery. The idea of antagonism between the two specialties might be due to the fact that the anaesthetic acted as a protective barrier between the patient and surgical assault, but this barrier was by no means impervious, and it was only by adjustment between attack and defence that adequate protection could be assured. Where surgery could be gentle, rapid, and dry, it was wonderful what an efficient defence was provided by other anaesthesia, but probably this method could not be used too freely without the risk of producing some ill effect, and for that reason it was important to limit, as far as possible, the extent to which the patient was saturated with ether. In that direction local anaesthesia and N<sub>2</sub>O might be of real service. Before local anaesthesia, either by itself or as an adjunct to narcosis, could come into more general use it seemed necessary that two conditions should be satisfied: surgeons would have to be convinced of its need, for without their full sanction its employment could not be considered for an instant; and great changes would be called for in the teaching arrangements. At present it was quite difficult to ensure that each student became reasonably familiar with the ordinary signs of anaesthesia, and it seemed to him that if a knowledge of local anaesthesia was to be acquired by him it would be necessary for the educational and examining bodies to reconsider the degree of importance which they intended to attach to this subject.

Dr. ALFRED E. BOYD (Dublin) said that one point in which they, as anaesthetists, failed too often was that they did not sufficiently study the psychology of their patient. When a patient presented himself for some simple operative procedure they were apt to regard the case merely as an incident in the day's work, while to the patient it was an event in his life. In many cases the patient dreaded the anaesthetic, with the surrender of personality involved, far more than he did the knife. Lack of sympathy between anaesthetist and

in the blood exceeded this barrier. But the barrier was not kept at a constant level, and the variation in the height of the threshold was one of the ways in which the kidney adapted itself to contingencies. A better word than "threshold" was "sluice," and the raising or lowering of this sluice could apparently be controlled through certain endocrines, and could be made to vary for one urinary constituent without involving another. The matter was not without its difficulties even on this view, and he thought it put merely to state that the pituitary regulated the out-put of water by some direct effect on the kidney cells, and that at present it was not known exactly how the balance between the water of the blood and the urine was struck. In recapitulation Dr. Langdon Brown supported Claude Bernard's contention that the object of all the vital mechanisms was to keep the internal environment constant. The nephridia originally were the principal means of maintaining a constant relationship between the internal and external environments. In evolution nephridia were replaced by analogous but probably not homologous tubules which formed the kidney, whose function might be defined as that of keeping the chemical composition of the body constant. Some nephridia were retained and modified to house the hormones which, previously less specialized, now played an important part in maintaining the internal environment. Not only morphologically but physiologically these modified nephridia recalled their origin. The last of them to retain excretory functions, the pituitary, still showed its association with such functions by the profound modification it was able to exert over the threshold of the kidney for water. It was probable that diabetes insipidus was due to the loss of this control, and possible that the overlying nervous structures influenced the matter through the pituitary; they certainly could do so without the intervention of the vasomotor system.

Dr. George Gannay raised the question why the action of pituitrin had been misunderstood for so long a time. All the original work on pituitrin showed it to be a diuretic. The misunderstanding arose by reason of the fact that the experiments on animals were carried out under an anaesthetic, in which condition the kidney vessels dilated and fallacious results were obtained. In watching the effect of pituitrin on the output of the urine it had to be remembered that the effect lasted for a limited number of hours, after which it ceased suddenly.

Dr. P. J. Caspary said that the effect of pituitrin had been worked out by a good many people, but there was one method of investigation not used before to his knowledge which Mr. Howard and he had been employing for a considerable time. They thought that some useful information might be forthcoming by some method of estimating variations in the concentration of the blood, if a method adapted easy to carry out could be arrived at. The method adopted was a steady diminution in the number of such cells following pituitrin injections. The changes in the concentration of the blood which occurred after injections of pituitrin were interesting phenomena worthy of much further investigation.

Dr. Laxapov Brown, in his reply, recalled how the point of view with regard to diabetes insipidus had changed within recent years, until finally the condition had come to be placed in two categories—namely, renal incapacity and some disturbance of the pituitary and overlying structures, and one or both of these derangements might be responsible for this extraordinary condition which was found so difficult to alleviate until the introduction of pituitrin treatment.

## HEMIPYPTORPHY.

The annual meeting of the Section of Diseases of Children of the Royal Society of Medicine was held on October 26th, with Mr. Angus Whitlock, the President, in the chair. A case of hemipyptorphy traced for fifteen and a half years was shown by Mr. P. Lockart-McKerny. The patient was first exhibited at the Royal Society of Medicine in 1906 (reported in Vol. 6 of *Children's Proceedings*, in the Section of Diseases of Children, p. 153), in collaboration with the late Mr. George Carpenter.

The child was then 2½ years old, and the left side of his body and head was growing faster than the right side. He was originally brought to hospital because he was walking late. There was apparently nothing else wrong with the child; his mental condition was normal and no abnormalities were detectable in the nervous system. The difference in length of the lower limbs was half an inch. The child was again exhibited before the Society in January, 1908. He was then very lame and there was a three and a half inches difference between the length of the legs. X-ray photographs showed the epiphysis to be more advanced on the left side than on the right. The child appeared to be two years older on the left side than on the right, and the left side of the tongue, the left eye and ear were all larger than the right. The child was lost sight of after this until recently, when he was found to be 21 years old, and as there was always considerable speculation as to what happens in these cases he was again brought before the Section. So far as Mr. Lockart-McKerny was aware this was the only case in which a child suffering from this condition had been traced to adult life. There was now only half an inch difference between the two sides. It was obvious that the small side was now "catching up" with the big side. Except on close observation one could not detect any difference between the two sides of the face or tongue.

Dr. F. J. Portman showed two cases, one of unilateral and one of bilateral congenital dilatation of the ureters. In the former case the diagnosis was confirmed by a post-mortem examination. The diagnosis was made in life by the aid of a cystoscopic examination, and by the x rays, after injecting 20 per cent. sodium bromide into the bladder and ureters. In both cases there was a gross infection of the urinary tract. The problem of the causation of the dilatation was discussed, and the majority of those present seemed to favour the presence of a spasm of the urethra. Dr. Dickinson Foxroze suggested the possibility of the spasm being analogous to that of pyloric stenosis. He thought it doubly interesting because the elder of the two children—and the case in which the condition was bilateral—was a girl. Mr. Max Price suggested that if the condition were analogous to pyloric stenosis it might be treated upon the same lines by section of the sphincter.

### TREATMENT OF INCONTINENCE OF URINE IN WOMEN.

A meeting of the North of England Obstetrical and Gynaecological Society was held in Manchester on October 13th, with the President, Professor Blaine Bell, in the chair, when Dr. D. Doreau (Manchester) read a short paper on the operative treatment of certain cases of incontinence of urine occurring in nulliparous women.

Dr. Douglas said that the degree of urinary control had been expressed by Taylor and Watt as:

- (1) Normal.
- (2) Fair—which was normal except on special occasions; for example, distension of the bladder, temporary vesical irritability, or times of mental or physical fatigue.
- (3) Poor—which allowed the urine to escape on any special abdominal strain, such as might be caused, for example, by coughing and active exercise; such patients were not most of the very little was retained in the bladder.
- (4) Lost—when urine continually dribbled from the patient, and three parts:

Taking the "poor" and "lost" groups only, the figures showed that about 8 per cent. of nulliparous women suffered from a disagreeable amount of urinary incontinence (Taylor and Watt). In this paper Dr. Douglas intended to deal only with those cases of active incontinence of urine which were due to weakness of the sphincter vesicae. He pointed out that the sphincter apparatus of the bladder consisted of important factor in sphincter apparatus.

All authorities were agreed that this was the most important factor in sphincter apparatus.

(1) *Intrinsic sphincter*, which was merely a specialized portion of the middle stratum of the bladder musculature. Its presence was even denied by some authorities.

(2) *Extrinsic or urethral sphincter*, composed of compressor urethrae, forming a complete muscular ring round the upper part of the urethra.

(3) *The supporting fibromuscular tissue lying between the base of bladder and the anterior vaginal wall*; this was made up of paravesical vascular sheaths and their connections, and was strongly

she had had a general anaesthetic he could not help thinking that she would have been deprived of the extra three years which were granted to her. There seemed to be no doubt that in brain operations a general anaesthetic was best avoided. For these he had used a 2 per cent. solution of novocain with the usual proportion of adrenaline. It enabled him to remove the segment of bone without pain, and avoided the terror of liability of post-operative vomiting. With few exceptions, when local anaesthesia was well administered, the fear of an operation on the part of the patient was diminished rather than increased. With eyes bandaged, and ears plugged with wool, together with absolute silence in the theatre, the patient should not be inconvenienced by more than the ordeal of lying on the table. By far the greater strain fell upon the surgeon himself.

Mrs. DICKINSON BERRY (London) urged the advisability of employing, especially in thyroid operations, local anaesthesia along with light ether anaesthesia. In using light ether anaesthesia the stimulating effect was maintained and there was no fall of blood pressure at the end of the operation. In ordinary ether anaesthesia there was a rise of blood pressure during induction, and a rise also when the patient began to come round and was allowed to strain. She deprecated the idea that a general anaesthetic was to be given only if the local anaesthetic proved unsatisfactory. The patient was apt to struggle and they did not obtain a smooth anaesthesia. In the employment of local anaesthesia the patient did not complain of pain, but without it complained of dragging sensations. These dragging sensations could be obviated by the use of light general anaesthesia.

Mr. BASIL HALL (Bradford) said that about 70 per cent. of his work was abdominal, and it was from the standpoint of the abdominal surgeon that he spoke. He always looked with great suspicion upon any anaesthetist who was a man with many "gadgets." He did not think it mattered very much, or at all, what percentage of the anaesthetic was administered. What he required was an anaesthetist who studied the patient, and who judged the patient, with no special reference to percentage and other formulae in regard to the anaesthetic substance. He deprecated also the use of mixtures, preferring simplicity. He thought that half the secret of satisfactory anaesthesia lay in a close association of the anaesthetist with the surgeon and an appreciation of both with the difficulties presented to them. He thought there was a tendency to push ether anaesthesia too far. What was wanted, in his judgement, was just enough and no more. Ethanesal was a valuable anaesthetic in so far as it was non-irritant, and produced less sickness than ether. After having tried other various experiences he had come back to the position from which he first started as an operating surgeon, and that was the employment of open ether anaesthesia, possibly, if necessary, preceded by a very small dose of heroin or of morphine, or a few whiffs of chloroform for induction. Local anaesthesia, he thought, he had given up for good.

Sir CRISP ENGLISH (London) spoke of the great importance of a discussion of this kind between anaesthetists and surgeons. He said that eighteen months' experience with ethanesal had convinced him that it was a decidedly better anaesthetic than ordinary ether. In the induction of anaesthesia in children and in nervous patients ethyl chloride was invaluable and prevented the distressing scenes which often blackened the first stage of anaesthesia; and gas and oxygen given by an expert with a proper apparatus was infinitely preferable to other forms of anaesthesia in a very large number of operations.

Mr. CHARLES PANNETT (London) was glad to hear emphasized the fact of delayed shock after ether. He himself would not acquit the anaesthetist, employing open ether, for all responsibility for the subsequent lung conditions frequently found. He had tried in St. Mary's Hospital to work a method of prevertebral anaesthesia. Its main disadvantage was the length of time—namely, twenty minutes—required for induction.

Mr. TROTTER, in reply, mentioned that morphine given in three small doses was of great value before operation and was also of great value in the use of local anaesthesia. He thought that the technique of local anaesthesia should be acquired by anaesthetists, and the practical work should be done by them, because there was always the possibility that their services would be required during the operation if a general anaesthetic were found to be necessary.

## VENTRICULOGRAPHY AS AN AID IN THE LOCALIZATION OF INTRACRANIAL TUMOURS.

I.—ADAMS A. MCCONNELL, B.A., M.B.,  
F.R.C.S.I.,

Surgeon, Richmond Hospital, Dublin; Lecturer in Applied Anatomy,  
Trinity College, Dublin.

THE cerebro-spinal fluid is secreted by the choroidal plexuses in the ventricles of the brain. It is absorbed from the subarachnoid space, chiefly from that part of it which lies in relation to the cerebral cortex. The only communications between the ventricles and the subarachnoid space are the foramina of Magendie and Luschka in the roof of the fourth ventricle. If a tumour be situated below the tentorium cerebelli it tends to press on the mid-brain, pons, and medulla, and so to cause some obstruction to the outflow of cerebro-spinal fluid through the aqueduct of Sylvius and the fourth ventricle (Fig. 1). Such obstruction leads to retention of fluid in the third and lateral ventricles and hence to their dilatation—just as obstruction to the ureter leads to hydronephrosis. If a tumour be situated in a cerebral hemisphere it cannot grow outwards because of the

FIG. 1.—T represents tentorium cerebelli. O and O represent the communications between the ventricular system and the subarachnoid space.

FIG. 2.—1, Skull. 2, Cerebrum in section. 3, Lateral ventricle. T and T represent direction of extension of tumours.

resistance of the calvarium; it grows inwards and sooner or later encroaches on the lateral ventricle so that the latter becomes deformed, distorted, or partially occluded (Fig. 2).

It is clear to anyone who has studied *post-mortem* specimens of intracranial growths that knowledge of the size and shape of the lateral ventricles would be of the greatest assistance in the localization of tumours during life. In July, 1918, Dandy<sup>1</sup> of the Johns Hopkins Hospital showed that it is possible to obtain radiograms of the lateral ventricles in the living subject. Since his paper appeared several cases in which his method has been used have been published in American journals, but with the exception of three cases published by me in April, 1921,<sup>2</sup> no adult cases seem to have been reported in this country. Fraser<sup>3</sup> has employed the method in cases of hydrocephalus in children.

### Principle of the Method.

If air be substituted for the fluid contents of one lateral ventricle and a radiogram taken, the air-filled ventricle will be clearly outlined on the radiographic plate in striking contrast to the dense calvarium, just as air in the intestine or pleural cavity is revealed on radiographic examination. When the photograph of one ventricle has been taken the head is slowly turned so as to allow the air to bubble through the interventricular foramina into the opposite ventricle, which is then photographed. If both lateral ventricles are dilated the tumour is probably subtentorial; if one lateral ventricle shows a deformity, that deformity is usually in close relation to the tumour.

this does not succeed the anterior horn may be selected for the next trial, in which case the patient lies prone with the head bent over the end of the table; as this is not a comfortable position, the first method described is usually chosen. In cases of cerebral tumour there is usually some indication of the side affected and the opposite side is chosen for the puncture. I have failed to find the ventricle by the method described above in two cases, one of a cerebellar tumour, the other of a growth involving both the middle and posterior cranial fossae. (2) So small a quantity of fluid is obtained that it is impossible to inject enough air to obtain a satisfactory radiogram. This has occurred in five cases. Three were early cases in which the needle slipped from the ventricle, but in these repetition of the puncture some days later gave satisfactory results. In two cases the instrument was used, and the ventricle found readily, but the fluid came away so slowly that the patients got tired of waiting.

#### Indications for Ventriculography.

If localizing symptoms be absent or if they have proved insufficient to guide the surgeon to the tumour ventriculography is indicated. No case of mine with a definite clinical diagnosis was submitted to ventriculography unless an operation had failed to find the growth.

#### Results.

I have attempted to perform ventriculography in fourteen cases and have succeeded in obtaining good radiograms in nine.

The following table gives the clinical diagnosis, the data gained by ventriculography, and the ultimate operative or post-mortem findings.

*Ventriculography Attempted.*

| Case. | Result of Operation.                  | Clinical Diagnosis.       | Radioscopic Diagnosis.                                | Ultimate Operative or Post-mortem Findings.                            |
|-------|---------------------------------------|---------------------------|-------------------------------------------------------|------------------------------------------------------------------------|
| 1     | Successful                            | Tumour—occipital lobe     | Tumour at junction of posterior and descending horns. | Operation: tumour at junction of posterior and descending horns.       |
| 2     | "                                     | None; no localizing signs | Tumour—posterior fossa                                | Post mortem: tumour posterior fossa, cerebellar.                       |
| 3     | "                                     | None; no localizing signs | Tumour—posterior fossa                                | Operation: cerebello-pontine tumour.                                   |
| 4     | "                                     | Tumour—occipital lobe     | No tumour                                             | Living two years after; symptoms not changed.                          |
| 5     | "                                     | Tumour—Rolandic area      | Tumour involving body lateral ventricle               | Post mortem: tumour internal capsule.                                  |
| 6     | "                                     | Tumour—frontal lobe       | Tumour involving anterior horn                        | Post mortem: tumour bulging into anterior horn.                        |
| 7     | "                                     | None; no localizing signs | Tumour occluding anterior horn                        | Operation: tumour frontal lobe                                         |
| 8     | "                                     | None; no localizing signs | Tumour—posterior fossa                                | Post mortem: sarcoma meninges posterior fossa.                         |
| 9     | Unsuccessful; too little air          | Pituitary                 | —                                                     | Post mortem: pituitary tumour.                                         |
| 10    | Unsuccessful; ventricle not found     | None; no localizing signs | —                                                     | Post mortem: very large cerebellar cyst; ventricles displaced upwards. |
| 11    | Unsuccessful; ventricle not found     | Cerebellar tumour         | —                                                     | Post mortem: dumb-bell tumour in Meckel's cave and posterior fossa.    |
| 12    | Unsuccessful; too little air          | Tumour—Rolandic area      | —                                                     | Operation: no tumour found.                                            |
| 13    | Successful                            | Hydrocephalus             | Communicating hydrocephalus                           | Operation: communicating hydrocephalus.                                |
| 14    | Unsuccessful; tipped superficial cyst | Tumour—occipital lobe     | Cyst in temporal lobe                                 | Operation: tumour and cyst in temporo-parietal region.                 |

Cases 2 and 8 died after eight and fourteen hours respectively, and Case 10 died on the operating table.

Of the nine cases in which air was introduced successfully into the ventricle, four had no localizing symptoms; in each

of these an accurate localization was obtained by ventriculography. One case had the symptoms of a tumour, but both ventricles were normal in shape and size, the subsequent course of the case has confirmed the radioscopic diagnosis. In the remaining four cases ventriculography gave more accurate information regarding the position of the growth than did the neurological examination, or exploratory craniotomy.

In five cases ventriculography was attempted but was not successful. In two of these the ventricle was not found because it was displaced from its normal position by a tumour. In two the amount of fluid evacuated was so small that sufficient air could not be injected to show in the x-ray plate. In one the cannula encountered a cyst 2 cm. deep; the fluid was withdrawn from the cyst and air injected. There was no indication for ventriculography when the extent of the cyst could be determined more accurately without it.

#### Dangers of Ventriculography.

Two of the cases in which ventriculography was successfully performed died. One sat up in bed suddenly eight hours after the injection and fell back dead. He had a large cerebellar tumour. The other died suddenly fourteen hours afterwards; at the post-mortem examination an infiltrating sarcoma of the meninges of the posterior fossa was found.

One case died on the table while the cannula was being passed; the ventricle was not found and hence no air had been injected. The pathological condition found was a huge cyst of the cerebellum, which flattened out the medulla and pons and raised the tentorium cerebelli into the shape of a dome. This pressure from below had displaced the lateral ventricle upwards so that the cannula had slipped below it. No lesion of any kind was found along the track of the cannula in these three fatal cases. It is noteworthy that in all three the medulla was grossly deformed by pressure.

Whether ventriculography has been performed or not no patient with symptoms of cerebellar tumour should be allowed to flex his head suddenly as he instinctively does when rising from the recumbent posture. Sudden flexion of the head is often followed by sudden death. My colleague, Mr. A. K. Henry, is about to publish a paper giving the anatomical and physiological reasons for this fact. It is questionable whether these fatalities can really be attributed to the method, as many cases of cerebellar tumour die suddenly; but they were fatalities.

Discussion of the end-results of these fourteen cases has nothing to do with the question of the value of ventriculography. All the cases came too late for effective treatment. Eleven were blind from advanced papilloedema or optic atrophy resulting from it, one had marked choked disc but was not blind, while two had no choked disc.

It is fair to assume that any manipulation is more dangerous in advanced cases than in those coming for treatment early in the course of the disease.

#### Conclusions.

Ventriculography in my hands when successfully performed has given definite and accurate information regarding the position of intracranial tumours. Ventriculography must never replace clinical methods, but in certain cases it is indispensable. Ventriculography is not without danger, but no treatment or lack of treatment is without danger in cases of intracranial tumour. Ventriculography is not simple, it is not to be attempted without a sound knowledge of the anatomy and physiology of the central nervous system. It requires much patience and minute attention to details. Above all, it must be performed with what appears extreme slowness.

If a competent neurologist cannot localize an intracranial tumour by clinical means, it is reasonable to put the possibilities—and the risks—of this method before the patient. It is also reasonable to assume that the risks will diminish with increasing experience. The alternative to accurate localization is death.

was found in the upper right parietal field, but the whole right hemisphere, which had been hardened *in situ* before removal, was greatly larger than the left. Figure 4 represents a coronal section through this brain,  $1\frac{1}{2}$  inches in front of the tumour. It will be noted that the right hemisphere is very considerably larger than the left although no tumour is present in the section. The amount of secondary oedema present varies from case to case, but it no doubt accounts for the high pressure met with in some cases where the actual growth is small. This is not the occasion to pursue this matter further; from our immediate point of view we see that the tumour, with the oedema, reduces the size of the ventricle and tends to dislocate it towards the opposite side, a process which is somewhat restrained by the pressure of the falx. From this brief general consideration of the physical characters of tumours of the brain one would infer that if we could in life get an estimation of the ventricular size and shape and position we should possess very valuable diagnostic or corroborative evidence.

### III.

My personal experience of ventriculography is limited to six cases. On one of these injection was practised twice, both times with a negative result, but without harm to the

FIG. 3.—Glioma of the left hemisphere, distorting and obliterating the left ventricle. The right ventricle is large and pushed over towards the right.

patient. I have had one death and that was in the case of a hydrocephalic child in an advanced stage of the disease. In this case I replaced 80 c.cm. of cerebro-spinal fluid with 80 c.cm. of air. A good picture was obtained of the dilated ventricle with air in the posterior fossa, proving it to be an example of "communicating hydrocephalus." The child died two days later, but it was already so far progressed in the disease that death at any time, with or without ventriculography, would not have been surprising. I should hesitate to use ventriculography again in a case of hydrocephalus in a child, as it is unnecessary. The case of which I speak was done two years ago. At the present time I think that the required information can be obtained by the use of dyes and suitable punctures. In the other five cases no untoward symptoms occurred. Valuable information of a corroborative nature was gained in two of these cases, in two it was not a help, and in one only was a positive diagnosis obtained by its means. A full account of this case is given below.

### CASE.

A young woman, aged 23, was referred from the Manchester Royal Eye Hospital, with papilloedema, and admitted to the Salford Royal Hospital on August 23rd, 1922. The patient had had headache and sickness for the previous two months. There were no previous illnesses of note. The patient was small, fairly bright, a "good witness."

**History.**—In the middle of June she began with what the family took to be neuralgia at the back of the head and left temporal region, also tinnitus in the left ear. She vomited severely at times. She had had slight malaise previously, but a severe headache came on in the street bringing vomiting in its train, and her companions had difficulty in getting her home. This was the first

thing that made her relatives think that there was anything seriously amiss; she improved with two weeks' rest. She went to the Royal Eye Hospital because her eyes troubled her. She was admitted there next day and was an in-patient for seven weeks, during which time she improved. Her sight used to go for two or three minutes and then suddenly improved again. She said that she felt very weak, and she was rather anaemic. She had no headache lately; it was previously mainly occipital, a little pain at back of eyes. She had not vomited lately. There was no nausea. She was dizzy, occasionally, but had never fallen. Her memory was very fair; she was always rather a slow girl, and found brain work more of an effort than it used to be. She was never drowsy, but sleeps well. Her temper was not good, not changed. She never lost consciousness, no twitching. There was no palsy, no tendency to fall in any particular direction.

**Examination.**—The pupils were normal,  $1\frac{1}{4}$  inch to  $1\frac{1}{3}$  inch equal. The palpebral fissures were normal; there was no squint, no ocular muscle palsies, no nystagmus. She had a slightly exophthalmic appearance, and a rather dusky look about the eyes. The cranial nerves, 1 to 12, were normal on both sides. There was no expressional palsy of face, no diminution of hearing on either side. Bilateral choked discs were present, the disc edge not visible, some striation, no haemorrhages, the vessels' exit not visible. Visual fields: there was concentric contraction which varied on different occasions. In regard to the arms, the grip was normal, equal, and there was very fine tremor (the patient seemed very nervous). The tendon jerks were active on the right, less so on the left. There was no paresis in any muscle group. The patient here stated that she had lately found her right hand go dead on several occasions without apparent cause.

FIG. 4.—Brain cut across 1 in. in front of a tumour, illustrating the ventricular distortion and the large size of the ipsilateral hemisphere compared with the unaffected one.

She was fortunately seen during one of these spells; no paralysis and no anaesthesia were detected—the condition was purely subjective. Finger-nose and finger-finger tests were well done. Rapid pronation-supination was badly performed on both sides. Bárány's deviation test was normal. Muscle tone in the arm was not decreased; in the legs it was increased. She walked fairly well, the motor power was good, there was no definite ataxia. The knee-jerks were active, clonic on the left but not sustained; there was no patellar clonus. Tonus was increased definitely, but not obviously in one leg rather than the other. Plantar reflex, right and left, was flexor. Oppenheim's test was negative. The heel-knee test was well performed, but movements were rather abrupt in both legs. In regard to sensation, there was recognition of a brush all over body, normal localization on the hands and arms. In regard to the joint-sense it was normal in the fingers and elbows on both sides. The positional test was normal. The patient now stated that she thought she had had some headache for ten months; it was worse in the morning, vertex and frontal, worse lying down; vomiting did not relieve the headache but occurred (as is usual with increased intracranial tension) when the headache was at its worst. The Wassermann reaction was negative. The urine was normal. After lumbar puncture in the centrifugized deposit, an odd small lymphocyte was found. With the perimeter both fields were charted, and concentric contraction was more marked on the left than the right, but nothing of outstanding interest was discovered.

Here, then, was a case with definitely increased intracranial pressure, believed to be a cerebral tumour. Localizing signs were absent. The attacks of numbness in the right hand pointed to the left hemisphere, but a careful examination on several occasions and by more than one person failed to reveal any physical signs to substantiate this. It was therefore decided to perform ventriculography and this was accordingly done on October 8th, 1922, 35 c.cm. of cerebro-spinal fluid being removed by ventricular puncture at Keen's point and air replacement carried out by Dandy's technique. X rays revealed a definite internal hydrocephalus. A ventriculogram (antero-posterior view) shows the two ventricles quite symmetrically dilated and rules out the possibility of a hemispherical growth. A subsequent exposure of

THE MOTOR SHOW AT OLYMPIA.

DEVELOPMENTS OF INTEREST TO MEDICAL MEN.

By H. MASSAO BUSH.

There are many developments of special interest to medical men in the seventeenth International Motor Car Exhibition promoted by the Society of Motor Manufacturers and Traders, which was opened under the patronage of the King yesterday (Friday) in the enlarged Olympia building, Kensington, London, and will remain available, Sunday excluded, until Saturday night, November 10th. The prices for admission are half a crown on both Fridays and Saturdays and free on all other days. The prices of the exhibits, alike as regards chassis and complete cars, are those which were fixed by the vendors, and which had to be reported to the exhibition organizers on October 15th. No changes, either in the way of increase or decrease, may be made during the period of the exhibition. The object of this rule is to let the inquirer know precisely how one product compares on the market with another under this head. This is the majority year of the organizing body, whose series of yearly shows, of course, was interrupted by the war. The new hall adds 65,000 square feet of stand space, bringing the total accommodation to 170,000 square feet, exclusive of the large amount of space needed to provide circulating avenues between the stands. Two other exhibition buildings in the kingdom claim to be larger. But when the figures are gone into it is found that the total area of the given establishment is returned, the implication being that that is available for stand space. The regulation forbidding members of the trade to smoke while on duty at their stands has been repealed. This is regrettable, for the building, large as it is, is crowded throughout the whole period it is open to the public, so that every effort should be made to keep the atmosphere pure. Why should those whose business it is to serve the public and who have wares to sell vitiate the atmosphere?

Over 500 Exhibitors.

This, therefore, is the first post-war exhibition of the sort which has been housed in London under one roof. In spite of the vast amount of space, it is not possible to accommodate all who would display. Several cases are performed excluded; and that after the space originally allotted, but since forfeited by firms which have gone into liquidation and are not eligible under the rules to display, has been redistributed. The natural lighting of the new building by day is all that can be desired, and the convenience of the additional entrance actually on the Hammer Smith Road will be greatly appreciated by the public. The new building has also made it possible to increase the catering accommodation, an improvement urgently necessary.

The total number of exhibitors is 526. There is a feeling this year that something should be done in respect of the British industry, the facts being that, on the one hand, it is in a very large percentage of cases placing vehicles on the market at less than the actual cost of production; and, on the other, that the number of passenger cars being absorbed by the buying public in this country this year is according to the latest registration figures, exactly double the maximum attained in the boom period before the war. The explanation of the paradoxical case of the British industry in general is that the majority of this increased business has gone to the foreigner, notably to the American trade, to which we are paying \$5,500,000 a year. Of course, the real cause is that, in the gross, there are far too many firms engaged in making passenger cars; and this is the only car-producing country in the world where the foreigner is able to do an appreciable business. America puts up an effective tariff wall against British cars despite the fact that her home industry is established on a scale producing 3,000,000 vehicles between January and September, 1923, hence the division of the manufacturer's dead charges over each car to sell reduces their very heavy in the case of a British manufacturer, to a negligible sum in the case of an American one. All the vehicles the U.S.A. sell in this country represent extra profit as far as that industry is concerned. The Continental exchanges, of course, favour

business in French, Italian, and Belgian cars in this country. German cars are not represented in this show, being still ineligible; but they are on our markets notwithstanding.

The Only Really International Show.

Most of the international trade organizations abroad are modelled on the pioneer body which promotes the Olympia exhibition. But they differ in one important detail. Ours is international in name and in practice; theirs are international in name, but not in practice. Thus a British manufacturer may be a member of the Chambre Syndicale in France; but he has no voting rights and, when it comes to exhibitions, he can be allotted stand space only when the native industry has been accommodated. No voting rights could be obtained by a British manufacturer belonging to any of the other national motor trade bodies, either on the continent of Europe or in America. By contrast, in this country the foreigner, or his representative, can be a member of the Society of Motor Manufacturers and Traders enjoying equal voting rights with British car builders and vendors, and the right to secure stand space at exhibitions under precisely the same conditions as obtain in the case of a native. Certainly there is abroad nothing in the nature of a spirit of reciprocity in this matter, a point concerning which the public in general appears quite ignorant. What the average citizen should realize is that we are sending money overseas for a number of commodities which we could produce at home. If we do not order from home sources tens of thousands of the dollar; hence there is a double bill to pay, one direct and the other indirect. The buying public should understand the proportions in which cars of different countries of origin are bought each year so that we may devote any increase in the sale of motor cars in this country to getting some of the out-of-work back into our factories. For instance, the capacity for absorbing motor vehicles in this country with a population of 47,000,000 must be in excess of 80,000 machines a year, particularly as the majority of the cars are small, low-priced vehicles. In this connection the enterprise of the British industry in pioneering this class of four-cylinder car must be borne in mind. America offers us nothing akin.

How Conditions or Use Govern Design.

All this would be more or less beside the point were the British industry charging for its wares sums out of proportion to their value relative to foreign producers. But it must be remembered that cars built abroad have to be suitable, primarily, for conditions obtaining in the countries of origin, and that, therefore, in certain respects the average foreign-built car cannot give the most suitable requirements of this country. It is for this reason that many types of British-built cars, designed with a special view to home service, have been found, year after year, to be unsuitable for conditions that obtain in the British market overseas. That is why America is supreme there to-day. In those countries of relatively few and, outside selected routes, of very makeability roads, the conditions are the same as obtain throughout the greater part of the United States. Cars designed to fulfil them have not many qualities desirable for home service. Further, from the New World there has not yet come anything that is equivalent to our small, relatively light weight, refined, and high efficiency constructions such as are low taxed and economical in fuel consumption. I do not refer merely to the small car as such, which, as has been pointed out frequently in these columns, is, on analysis, commonly a car of cramped accommodation. Some examples of such practice come to us from the Continent. Nevertheless, most of the pioneering has been done in this class, as distinct from the cycle car, which is of no interest to the medical man. America has never tackled this problem for the sufficient reason that the conditions of her highways and byways render it impossible to find a home market for this class of goods.

The first message of this motor show to the medical man with a strictly limited sum to spend on his car concerns the so-called light cars that are small cars, but which will

of the child is essential before an anaesthetic can be administered.

Acetonaemia may be defined as a disturbance of metabolism which is manifested by the excretion in the urine of acetone, aceto-acetic acid, and  $\beta$ -oxybutyric acid. It is undoubtedly more readily produced in children than in adults. Down to the time of Frew's investigations the condition was chiefly recognized in adults in connexion with diabetes, wasting diseases, and starvation. In the adult it was known that acetonaemia was induced by abstinence from, or deprivation of, food, or by elimination, or by carbohydrate starvation. We know now that acetonaemia may be induced in children by very trifling causes, and, in its slighter form, may result from apparently insignificant changes in the dietary. Dr. R. S. Frew examined the urines of all the children in the Hospital for Sick Children, both medical and surgical cases, from the day of their admission over a considerable period of time. None of these had acetonuria on admission (I am excluding the diabetics), but no less than 62 per cent. of them showed the presence of acetone in the urine during the three or four days following admission, and it had no obvious relation to the disease from which the child was suffering; the maximum of the action occurred, on an average, thirty-six hours after they had entered the hospital. The babies under 1 year of age and the older children showed the reaction to a lesser extent than those between 2 and 6 years. But in all cases it cleared up within a week. Frew attributed the temporary acetonuria to the change of diet and a temporary loss of ability to assimilate carbohydrates, but chiefly to the fact that the standard hospital diet contained relatively less carbohydrate than the children had at home. It was further explained by the relative immunity of the infants when they were fed exclusively on milk, both at home and in hospital, and confirmed by the condition being absent in the children from 10 to 12 years of age, when their diet in hospital more nearly approximated to that in their own homes. Frew further found that when a child had glucose added to the dietary from the time of admission the acetonuria did not occur.

It would be well here to describe the clinical aspect of acetonaemia, for it is an especially frequent occurrence in children after anaesthetics have been administered. It also occurs in pneumonia, in cases where large doses of salicylates have been given, in cyclical vomiting, and, of course, in diabetes. Slight cases may occur where there is no symptom, and only detection by a urinary test can elicit its presence. But in its severer form the symptoms are, in order of their frequency, vomiting, increased pulse rate, restlessness merging into excitability and delirium, air-hunger, and sunken eyes; later, acetone can be detected in the breath, black urine is voided, and collapse occurs as a final issue.

Looking back on the years before this condition was recognized one can remember cases that died after anaesthetics with the above sequence of events; and so our deepest gratitude is due to Frew's work, which has enabled us to prevent its occurrence by administering glucose before operation, and by abandoning that custom, now happily relegated to the past, of starving a child before an anaesthetic is to be administered. It also has enabled us to counteract the symptoms when they do occur by increased administration of glucose, by the mouth where this is possible, and in a 5 per cent. solution of glucose in saline per rectum as well.

The striking *post-mortem* feature of the fatal cases of acetonaemia is the change shown in the liver. To the naked eye the cut section of the liver is pale, and the surface is oily. Microscopically there is marked fatty degeneration of the cellular elements.

The functions of the liver cells are still far from accurately known, but it is becoming more clearly recognized that they are of prime importance in relation to body metabolism, and the profound changes met with in acidosis are convincing evidence of this. It would appear that the liver is the great storehouse of the body fuel reserves, and, at the same time, the "quartermaster" controlling their distribution. Certain conditions serve to deplete the storehouse, and the "quartermaster's" functions are sadly disturbed.

As to the practical application of this to our everyday work of administering anaesthetics, one feels that this aspect of children's surgery is not sufficiently recognized, and I am convinced that much discomfort and danger to children can be avoided by attention to it. The fatal cases are usually noted, but the tragedy is that once the severe symptoms have actually arisen, the march of events is apt to be dramatically rapid, and any treatment unavailing. The successful tackling of this danger is dependent on prevention, or, at least, on early recognition. In the old days, before the condition was recognized as acetonaemia and acidosis, the symptoms were said to be due to "delayed chloroform poisoning," and in textbooks to this day the *post-mortem* appearances of the liver will be found under that heading; but we now know that the true cause is carbohydrate starvation, and find that it can occur after the administration of ether as frequently as after chloroform, and even after spinal analgesia.

#### Preventive Measures.

1. When acetonuria is present the operation must be postponed until treatment has cured the acetonaemia, because this condition is seriously aggravated by an anaesthetic.

2. All cases prior to being anaesthetized should have glucose as a routine measure for at least two days before the operation, and should continue to have the glucose administered as an after-treatment.

3. The patient must not be starved before operation.

4. Aperients or purgatives must not be given before operation.

In all cases before the administration of an anaesthetic a hypodermic injection of atropine sulphate should be given. The dosage, according to age, is:

|                                     |     |     |             |
|-------------------------------------|-----|-----|-------------|
| During the first six months of life | ... | ... | 1/400 grain |
| During the second six months        | ... | ... | 1/200 "     |
| During the second year              | ... | ... | 1/150 "     |
| From 2 years of age upwards         | ... | ... | 1/100 "     |

A smaller dose than this is inadvisable. The child tolerates atropine well, and it is essential that the narrow airway should be free from secretions. It is most efficacious when administered half an hour before the anaesthetic is started.

Morphine is a dangerous drug for children, and my only advice concerning it is that it should never be used before administering an anaesthetic to a child.

#### CHOICE OF THE ANAESTHETIC.

So much has been said and written concerning the comparison in value and safety between chloroform and ether that I do not intend to go very deeply into this now. Suffice it to say that, at the Hospital for Sick Children, Great Ormond Street, we have come to the conclusion, without any manner of doubt whatsoever, that for children ether (preceded by a hypodermic injection of atropine) will always be the "anaesthetic of choice." The comparative safety of ether administration over that of chloroform is enormous.

The conditions met with in adults that contraindicate ether, such as brittle arteries or very high blood pressure, are not met with in children. The only condition where chloroform should be given instead of ether is when a cautery—electric or Paquelin—is to be used, and owing to the inflammability of ether that anaesthetic has perforce to be avoided.

A point to be remembered concerning the inflammability of ether vapour is that care must be taken that a naked light of any kind must be excluded from the room, because the vapour seems to permeate to a distance surprisingly remote from the anaesthetist or his table. The anaesthetist must always be alive to this real source of danger. When there is a fire in the grate, as must often happen at "private" operations, the anaesthetist should always take up his position with his belongings as far away from the fire as is possible; and he should never omit to take the precaution, which is absolutely necessary, of hanging a wet towel or sheet in front of the fire so that the ether fumes may not reach it. Should he have that most unpleasant experience of being in an ether fire, it is well to

as far as the accessory maker can render it possible for the car builder to lower his costs. One idea of certain accessory makers, of course, is to get their wares on quantity production schemes, then go to manufacturers on a lesser scale and point out to them that such and such a popular car-builder has placed orders and that, therefore, they will be out of the fashion if they do not have the given accessory. Another aspect is that if the vendor gets a given accessory on quantity production cars, when each renewal is needed the private motorist will buy that accessory—not at the figure at which the car-builder has acquired it, but at a price which will reimburse the accessory maker for the loss he has incurred in supplying the car in the first instance. It is a weird and unhealthy way of business, and I am satisfied from my own investigations that the really sound firms in the accessory industry are standing by and letting anybody's accessories be thrust to the fore, or jettisoned, as they see fit. The state of the exchanges greatly complicates this matter. In connection with steel and other raw materials these will tend rather to rise than to fall.

#### FACTS THAT MAKE THIS A MEMORABLE EXHIBITION.

The outstanding general tendencies this year are, not that there is any appreciable number of new models worthy of attention in what are called the small car classes, but that the smaller middle size chassis, rated anywhere about 14 h.p., is attracting the attention of an increasing number of sections manufacturers, many of whom are lifting important fresh contributions under this head, each at moderate prices and designed especially for the owner-driver. There is the new 12/30-h.p. Sunbeam, designed much on the lines of the already well known 14/40-h.p. type—but without front wheel brakes—which is listed with 4-seat body equipped completely at £570. This is in every sense a new Sunbeam product as regards quality. Then there is a new 4-cylinder side valve engine 14-h.p. Bean car with four speeds forward and right-hand control, complete with 4/5-seat body, at £595; and a new 14-h.p. overhead valve 4-cylinder engine 13/25-h.p. Armstrong-Siddeley car, listed complete as a 4/5-seater of uncommon ample accommodation at £560; the design of the latter is quite unconventional but sound. It is of light weight, the idea being to put on the market a British-built car that will compete with American machines without, however, attempting anything so absolutely futile as to imitate transatlantic methods of construction. The Armstrong-Siddeley is intended to be suitable both for the overseas and for the home markets, and to provide those particular aspects of refinement characteristic of the British car of the higher grade which it is not possible to embody by American methods of construction. This machine works out economically as to prime cost, tax, fuel, lubricant and tyre consumption, irrespective of price. The machine works out economically as to prime cost, tax, fuel, lubricant and tyre consumption, irrespective of price. The machine works out economically as to prime cost, tax, fuel, lubricant and tyre consumption, irrespective of price. The machine works out economically as to prime cost, tax, fuel, lubricant and tyre consumption, irrespective of price.

In general there is certainly an increasing desire on the part of the designer to provide more accommodation for the driver and passenger on a motor car. We see this not only in such schemes as have been mentioned already, but also in the Wolseley development of some moderate priced, middle size models wherein the chassis width has been increased and therefore wider bodies have been possible. We have the same effect, too, in the relatively wide new 14-h.p. Armstrong-Siddeley. Another point which is important to the medical man is that there is a tendency not merely to answer the general demand for right-hand control of the brake and gears—the central control is often

unaisance, especially in the season when heavy coats have to be worn—but also to provide, in the case of middle-powered cars, four speeds forward on the Continental principle, instead of three, which has quite a vogue in this country and which is still very popular in America. Three speeds are adequate to certain constructions provided the engine has flexibility and pronounced acceleration and that the power-weight ratio is favourable. But this is rare. Wolseley this year has furnished four speeds to the 15-h.p. overhead valve, 4-cylinder engine type and many another example of this could be cited, alike in models already familiar and among entirely new types, as witness the 14-h.p. Bean, the new 15/30-h.p. 6-cylinder Manxley, and the new 21-h.p. overhead valve, 6-cylinder engine Land-rover, which last is of interest rather to the specialist than to the general practitioner; as is the new 21-h.p. 6-cylinder four-speed Rover and the new 20/50-h.p. four-speed Sunbeam. For the medical man's service it is essential that a car should have a quick acceleration without straining the engine, which may often be cooler than the precise temperature that represents its most efficient working and the most favourable condition of the lubricant as to viscosity. Most modern engines will "open up well"; but when relatively a short distance has to be run, and comparatively long spells of idleness for the car between stages, so that it is often possible to assist the mechanism appreciably by having four speeds instead of three. The doctor's problem is much the same as that which has concerned our great passenger-carrying corporations, including the London General Omnibus Company, whose difficulty for years past has been, not how to make vehicles that will travel faster from rest to the normal running speed in minimum time. That is how time is saved between halts. Nobody wants to travel at a mile a minute on his ordinary occasions; but most medical men want to get going from a stand to twenty miles an hour in as few yards as possible. That is where the four-speed gearbox use of a "hot spot" in connection with the carburettor.

Chassis Lubrication Made Easy. Another point of economy is the welcome spread, especially in regard to middle size and small cars, of great gun lubrication which was taken up by a few manufacturers last year. Now it is standardized by nearly half the builders of British cars at a popular price. Already it is plain that it will be a universal practice in two or three years. This method ensures the positive entry of the lubricant to the point of the chassis which it is desired to lubricate, and it is made possible to get at those points which have been inaccessible, thereby directing the operator, yet, hitherto, failing to achieve the object in view. Overhead valves continue to increase gradually in favour, and it is to be noted that this year these firms employing the system in fresh types are more or less all justified in that they are obtaining greater economy and greater power, which is more than could have been written truthfully about a number of firms that have produced cars with overhead valve engines in past years. The reason appears to have been that it was considered that it would be a selling point despite the fact that the given builders had not gone to the pains, or expense, of acquiring any first-hand knowledge of the will and wherfore of this system of design. The greatest of all mechanical developments of the year is the wide exploitation of brakes to all four wheels. These are not necessarily required by medical men. Certainly members of the profession must be warned seriously concerning many front wheel brakes furnished to the cheaper classes of cars, again very obviously because it is foreseen that there is to be a vogue for this class of braking. Certain manufacturers are putting such accessories on their cars without themselves having had sufficient experience to be able to appreciate all the problems involved if the system is to be made satisfactory. If it is not, I maintain that it is a positive menace to road users. There are to be seen at Olympia many cars, especially of the cheaper sort, fitted with four-wheel brakes which will prove dangerous. Unfortunately for our purpose, the law of libel does not allow me to specify them.

(between the "blows") will partly anaesthetize the soft palate. Then slowly drop the ether on, drop by drop, holding the facepiece quite six inches from the face, the end tilted below the chin. Do not hurry the early administration. Always have a small blanket on the chest in such a way that it can be adjusted around the side of the child's head, because the ether vapour is heavier than air, and so will fall below the level of the upper surface of the face, and your endeavour is to try to keep this from escaping below the required level. "Go slow" until you have the child unconscious, then push the anaesthetic further by saturating the gauze with ether and covering up the head with the small blanket that is arranged about his neck. And remember this—always and at all times have a free airway. So long as the jaw is forward and the tongue not back you can hear by the free easy breathing that the airway is good. And so long as the airway is clear the colour must be right.

It must, however, always be borne in mind that the child's air passages are minute compared with those of the adult. On this account there is a smaller margin for error when anything tends to obstruct those air passages. The slightest obstruction to a free airway tends to make the child cyanosed, which means the right heart is being distended, and this cardiac embarrassment is a real danger. So the importance of maintaining a free airway cannot be exaggerated. I would maintain that the sudden death of a child during, or immediately after, open ether administration is generally (if not always) due to the heart strain that has accrued during some part of the operation secondary to an insufficient oxygen intake.

#### RECOVERY.

A few points I would mention to render the child's recovery from anaesthesia less unpleasant are the following:

1. A drop of *ol. ricini* in each eye. The eyelids are so dry and the suffusion of the conjunctiva so evident after lengthy administration of ether, that conjunctival trouble is not unknown, and this will be prevented by the use of *ol. ricini*. It should only be used after the ether administration has ceased, because otherwise an ethereal oil will be formed which is itself damaging to the conjunctiva.

2. The dryness of the mouth so frequently complained of may be prevented by sponging out the mouth with normal saline immediately the administration has ceased. This is particularly necessary after operations about the mouth—for example, tonsils and adenoids—when it is the coagulated blood on the tongue and palate which, when left, is the source of annoyance to the child, and can be obviated by this means.

3. The highly strung, nervous child will recover from the anaesthetic more quietly, and have a longer sleep after consciousness has returned, when a rectal sedative is given. For a child of 10 years, potassium bromide 20 grains and aspirin 10 grains, in half a pint of normal saline, should be given slowly per rectum before consciousness returns, as soon as the child is put back to bed.

My object has been to draw attention to the above few practical points in the hope that my fellow practitioners may be enabled to help their little patients to take an anaesthetic with safety and with as little unpleasantness as possible.

#### DISCUSSION.

Dr. A. L. FLEMING (Bristol) said that deaths were attributed to ether and to delayed chloroform poisoning which were really due to acetonaemia. With regard to constipation and the use of aperients, certain school children, and more especially anaemic girls of 15 or 16, could have operations obviated or at least delayed until the patient was in a more suitable condition for operation, if, when the colon was loaded, the breath foul, and a diagnosis of doubtful appendicitis made, they were put to bed and purged. In many cases school children were apt to be constipated, and if a purge was not given and the bowel was not emptied before operation they were liable to salivate excessively and to require more anaesthetic than if a purge was given. There should, however, be an interval between the giving of the purge and the anaesthetic. He also asked Dr. Sington whether his cases were anaesthetized

by daylight or by lamplight, as there undoubtedly were differences to be noticed in the colour changes under anaesthesia as induced in the presence of different illuminants.

Dr. WILKINS said he failed to understand why Dr. Sington recommended ether for tonsil and adenoid guillotine operations in children, as he personally found gas and oxygen sufficient for a dexterous surgeon, and far better for those unfortunate children who still were operated upon as out-patients.

Dr. C. H. MOTT (Burslem) inquired whether cases which developed acetonaemia in hospital cleared up without treatment. He wished to know also whether chloroform was no more dangerous than ether in such cases of acidosis where operation could not be delayed. In his own practice he made use of gas, oxygen, and ether, and he noticed that even with these anaesthetics some cases developed acidosis.

Dr. HENRY FEATHERSTONE (Birmingham) said he was inclined to believe in an important third factor in the production of acidosis in addition to starvation and drugs—namely, individual idiosyncrasy, which might be an inherited characteristic. He instanced the case of a little girl, aged 4, the apparently healthy daughter of well-to-do parents, whose tonsils and adenoids were quickly removed under a single dose of ethyl chloride. Marked symptoms of acidosis and toxic vomiting appeared within forty-eight hours, and the child died on the third day. In that case the effect of starvation and drugs must have been small, for the patient only omitted her breakfast on the morning of the operation, and milk was given the same evening, while the anaesthetic was quickly eliminated. An elder brother had shown signs of acetonaemia a year or two previously. Many thousands of children whose tonsils and adenoids were removed in hospitals were dealt with before a case of this kind was met. He agreed with Dr. Sington that gas-oxygen was the anaesthetic of choice for babies who were to undergo Rammstedt's operation for hypertrophic pyloric stenosis. At the Birmingham Children's Hospital very good results had been obtained, and the last ten cases in the private ward had all recovered. The latter result was no doubt largely due to the early diagnosis and more satisfactory state of nutrition of the infant, but nevertheless the entire series showed a most satisfactory recovery rate. Ethyl chloride was his routine anaesthetic for dental extractions in children, and he anaesthetized about 2,000 such cases in the course of a year. He entirely agreed with Dr. Sington that rapid induction and rapid elimination were the secret of success. Laryngeal stridor or lingual obstruction might lead to some signs of shock and to after-vomiting.

Dr. L. A. MOORE (Bristol) asked for details with reference to the administration of gas and oxygen to children, and whether ethyl chloride was advisable as a prelude to ether induction.

Dr. SINGTON, in reply, said he was glad that the subject of acidosis and constipation had been so freely touched upon. In his opinion poisoning due to liquid faeces was rather different from that due to hard faeces. Toxicity due to liquid faeces was much more serious than that due to hard faeces. Purgation should, therefore, be employed with great care, and if possible some time before the operation was undertaken. The child would stand a better chance if operated upon in a constipated condition than if its colon was full of liquid faeces the result of purgation shortly before. He then answered the questions asked by his critics in detail.

#### FATALITIES FROM ANAESTHETICS.

BY

ARTHUR LAUNCELOT FLEMING,

M.B., CH.B. BRISTOL,

Senior Honorary Anaesthetist, Bristol Royal Infirmary.

STATISTICS of deaths under anaesthetics are generally so lacking in essential details as to be of little use for guiding us in our practice. After examining quite a large number of these reports with the intention of reviewing the

INTERCHANGEABLE COACHWORK.

Unquestionably that is the most notable fresh contribution to the problem of coachwork made this year. It is important to observe that these advantages are all obtainable for a lower price than an ordinary covered body. The medical man can have the advantage of using a complete saloon on a chassis which otherwise would be somewhat overloaded with a cabriolet, or coupe, which is bound to become creaky in relatively short time. Moreover, as far as tests have gone, the Weymann bodies have been found capable of withstanding extremely varied climatic conditions such as great heat in the day and cold at night. The wrapping that occurs in such circumstances is temporary only, for the body recovers its normal form with the subsequent change of temperature. Of course there are other developments of coachwork schemes as standardized on low-priced vehicles. There has not been much improvement as far as open types of bodies with collapsible hoods and temporary side curtaining schemes are concerned; the chief improvements have been in the direction of eliminating rattle and rendering more simple the process of fixing. Observe in this connection the improvements made in the series of Standard cars. Moreover, interchangeability of component body parts has been achieved, and this firm has devoted a special factory to the building of these bodies. Thus, in the event of a door, or a panel, or window, becoming damaged in an accident, the replacement is as quick, prompt, and economical as possible, in that the given part has merely to be ordered and it will be found that it fits in position exactly. This is made possible by the developed methods of construction and by the materials employed. These bodies are better made as to certain details than transatlantic bodies; certainly, America has not attempted anything so simple and efficient from the point of view of replacement of parts.

STURDY DEVELOPMENTS IN DETAIL.

The wheelbase of the Dodge has been increased to 9 ft. 8 in., the body is lower, and the rear springs, which are now of the undersprung semi-elliptical type, have been increased from 45 to 55 inches in length. The front ones are also longer as well as wider, being built up of more and of thinner leaves. The brake pedals are larger, the hand-brake and gear levers have been moved forward, giving more leg room and making it easier to get in and out of the body; a Yale lock has been built into the transmission, rendering it possible to double-lock the car when not in use. The steering wheel has been improved in appearance, all the electrical connections being inside the column. Louvers have been provided in the sides of the bonnet and the grouping of the instruments on the board is improved. Drum type headlights are employed to harmonize with the new and greatly improved body lines, and a combination of tail lamp and stop signal is mounted on the license plate bracket on the rear cross member of the frame. This lamp operates automatically, being a valuable "safety first" device. The seats providing more leg room, being equipped with deeper bodies are now longer and lower, being equipped with deeper automatically, being a valuable "safety first" device. The rear cross member of the frame. This lamp operates automatically, being a valuable "safety first" device. The seats providing more leg room, being equipped with deeper bodies are now longer and lower, being equipped with deeper

Four types of 4-cylinder De Dion-Bouton touring chassis are marketed this year, the 12/24-h.p. being a side valve engined type, the 12/28-h.p. an overhead valve engined type with brakes on all four wheels; the 15/43-h.p. type having overhead valves with four wheel brakes and cantilever rear springs; and the 22/55-h.p. type also has overhead valves and four wheel brakes, together with cantilever rear springs. The first named chassis costs £530, a reduction of £51 7s.; and the complete 3/5-seated all-weather torpedo £540. The 12/28-h.p. model with overhead valves has a wheelbase 4 inches longer, the chassis costing £445, which represents a reduction of £66 7s., from which £20 more can be deducted if front wheel brakes are not desired.

A CONTRAST IN TYPES.

The Renault range for 1924 includes five chassis; the wheels—disc, wire, and steel; and so on. Incidentally, the Society of Motor Manufacturers and Traders has requested

6-cylinder power plant. The smallest in size is the 8.5-h.p. type with 3-seat body, or with two seats and dickey, at £265 complete in each case. The developments in these chassis were dealt with in these columns on the occasion of reviewing the Paris Salon. This firm is one of the three pioneer small car makers of France. A remarkable mechanical development is that some of the practice of the small cars is now applied to the larger and most expensive vehicles also. Of course, the larger types have brakes to all four wheels; only the smallest one is lacking them. The horizontally opposed, twin water-cooled 4-cylinder engined 9-h.p. Ariel chassis, that was introduced last year, remains unaltered, and in the interval has scored 100 per cent. success in the light car class in the London-Lands End trial. The single shell body standardized has been improved considerably, the rear seat having been widened so that two adults can be accommodated. The retail price of the standard vehicle with 4-seat body is £165 only. What is styled a *de luxe* model—the buyer having the choice of three colour schemes and the standard equipment—embarrasses the manufacturer. It is sold at £160, or, if the Lucas electrical engine starter is provided, for £112 more. The 10.4-h.p. side valve engined 4-cylinder £111 tax Calcott model is now shown as a 2-seater and dickey type with all-weather curtains for £265 only, a single shell body type being listed at £20 more. In the second named occasional seats are provided behind the two front ones. Sundry mechanical improvements have been incorporated in the 11-h.p. 4-cylinder side valve engined Hillman chassis, including a dry plate clutch with a neat form of withdrawal gear; also a compensating gear for the brakes. The prices of the 2-seat and 4-seat types have been reduced by, approximately, £50 each, yet the engine running has been improved and the brake application is also praiseworthy. The generously padded upholstery is of real leather and the angles of the seats are well planned. The side panel equipment is now all of metal work finished in dull black, instead of nickel plate, thus reducing the labour of cleaning. The rear side panels can be joined together across the car to form a screen for the back seat. A useful fitting is the provision of a two-way tap in the fuel tank whereby it is possible always to have a reserve of one gallon. The 2-seater is listed at £350 and the 4-seater at £3 more. The list of new British car types includes a side valve engined 2,121 c.c.m. 4-cylinder Arrow-Johnson listed complete at £398; and the Cluiey (2,150 c.c.m.) Hands (1,870 c.c.m.), Meteorite (1,753 c.c.m.), and Whitlock (1,753 c.c.m.) 6-cylinder cars.

"COMFORT."

As at the Paris show, so on this occasion, a novelty of note is introduced by the enterprise of the tyre industry, notably that of the Dunlop Company in the guise of "giant" section tyres designed to be run at low pressures with safety. The aim is really for the tyre industry to assist the chassis manufacturer in the matter of comfortable suspension; to be quite plain, to hide faults of bad suspension. Hence the part of many Continental manufacturers of small cars on the demand for large section, low pressure tyres on the have to deal with very bad road conditions and, therefore, have to make their springs much harder than we are accustomed to in this country. It would be an unsafe movement were it not for the fact that the corded system of construction renders the covers very much stronger than before, and that the principle takes into account the stresses of corner work, and so forth, these large section tyres fitting on proportionately very wide rims. Interesting experiments have been carried out in France concerning the effect of these tyres; they have been punctured in racing at a mile a minute without ill consequences. But the majority of Continental expert drivers who have tested them consider that they exercise a certain effect on the steering. Against that the gain in riding comfort is admitted. The Dunlop Company experimented with this type as far back as 1916, when it fitted a 13.9-h.p. Rover car with a set. There are many other exhibits on the stand of this firm, including all the corded sizes; three types of wheels—disc, wire, and steel; and so on. Incidentally, the Society of Motor Manufacturers and Traders has requested

gr. 1/100, morph. sulph. gr. 1/6, atropine sulph. gr. 1/180; "Hyoscine compound B" contains hyoscine hydrobromide gr. 1/100, morph. sulph. gr. 1/4, atropine sulph. gr. 1/150. The injections are given half an hour before the time of operation. The patient is then anaesthetized with gas and oxygen, and the anaesthesia deepened with ethanesal or mixture until the breathing is deep, regular, and slightly stertorous; the colour should always be pink. The face-piece is then removed; a gag placed in the mouth for such cases as enucleation of the tonsils, and the anaesthesia is continued by means of a tube placed in the mouth.

One of the astonishing things about this method is the small amount of mixture necessary to maintain the requisite anaesthesia. Indeed, in a certain proportion of cases hardly any mixture at all is necessary for the rest of the operation—that is to say, after the facepiece has been removed; after that, gas and oxygen alone is sufficient.

In this connexion I must mention that there is one particular type of case where I have been forced to use chloroform alone as my adjuvant. I refer to cases of diathermy. In our throat department Mr. Harmer is treating cases of carcinoma of the tongue, fauces, etc., with the diathermy cautery, and, I gather, with excellent results. Now occasionally in these cases there is a certain amount of sparking, either accidental or intentional, and so one cannot have any ether in the adjuvant bottle lest there should be an explosion, and must use chloroform.

In a large number of cases the best way to continue the anaesthesia is to pass one or two small rubber tubes through the nostrils, and pass the anaesthetic into the post-nasal or endopharyngeal space; I do this by means of a metal stirrup and tubes.

For operations such as submucous resection of the nasal septum, after anaesthesia has been obtained—and here let me say that in nose and throat work as well as in abdominal work I think that it is essential to get the patient "well under" before the operation begins—an artificial airway is placed in position and the anaesthesia continued by what really is an endopharyngeal method. An airway devised by Mr. Clausen, one of our residents at St. Bartholomew's Hospital, is one of the best I have ever seen; the anaesthetic is delivered at the upper opening of the larynx, and the return air is diverted by a tube away from the operator and anaesthetist.

The results that I have obtained so far with endopharyngeal gas-oxygen-ethanesal have been most encouraging, and I hope in the near future to develop the method still further. The endotracheal administration of gas-oxygen-ethanesal is another recent development of the method, and one that appears likely to be very valuable for work not only in the mouth and neck, but also for upper abdominal cases, since relaxation of the abdominal muscles is readily obtained. Sufficient work, however, has not yet been done with this method to warrant me at this early stage to go into details.

#### DEMONSTRATION.

Dr. CHRISTOPHER MAYHEW (Southsea) showed a new apparatus of his own invention for administering warmed ether vapour, the chief advantages for which were claimed to be its lightness and portability, the whole of the apparatus, weighing only 1 lb., being capable of being taken to pieces and stored in the warming cylinder.

## THE TREATMENT OF HAEMORRHOIDS BY INTERSTITIAL INJECTIONS.

BY

JOHN DUNBAR, M.B., Ch.B.,

UNIVERSITY ASSISTANT TO THE REGIUS PROFESSOR OF SURGERY,  
GLASGOW UNIVERSITY; SURGEON TO THE OUT-PATIENT  
DEPARTMENT, GLASGOW ROYAL INFIRMARY.

A great interest has recently been aroused in the treatment of haemorrhoids by injection of carbolic acid, I wish to record my observations and conclusions drawn from a series of 150 cases treated in the Royal and Western Infirmarys, Glasgow, during the past year. These patients were kindly sent by the various surgeons of the Royal Infirmary, and Sir William Macewen permitted me to treat haemorrhoidal cases in his wards in the Western Infirmary.

The treatment consisted in the injection into the pile of 1 per cent. carbolic acid in liquid extract of hamamelis. At the Annual Meeting of the British Medical Association in Glasgow (1922) the method was demonstrated in Kay's wards in the Glasgow Royal Infirmary by Mr. Star of the London Hospital.

No cases were not selected; all degrees of piles were treated, from the simple internal piles with no prolapse to those with marked prolapse. The class of patient treated consisted chiefly of manual workers engaged in such arduous occupations as mining, engineering, and labouring. The ages of the patients varied from 21 to 70 years. The number of injections needed to effect a cure did not seem to depend on the age of the patient or the duration of the complaint. One patient who had been suffering for one year required seven treatments, another case of fifteen

treatments needed only five. The number of piles treated varied, and the greater the number of piles the longer the duration of treatments. The size of the piles varied from the size of a pin to the size of a finger. The larger the pile the fewer injections. Bleeding usually stopped after the first injection. In only one instance was a second injection needed for this symptom, although "bleeding piles" comprised 40 per cent. of the cases. Haemorrhage after injection through the puncture of the needle is slight, and I have not seen a case where bleeding, due to the treatment, has been of any of the special forms of arresting the haemor-

rhage described by Dudley D'A. Wright in the second edition of his pamphlet on this subject. Where inflammation was marked no injections were given until this was subdued; if only slight, injections were given, and although the pain following was more marked than usual it was never severe and the piles quickly underwent thrombosis.

Immediately after injection the piles swelled; the mucous membrane over some of them became blanched; and where external piles were also present the external pile corresponding to the internal one injected also became swollen in many instances. In only four cases did the treatment keep the patient off work, the duration of incapacity being two days, three days, two weeks, and one week. In these cases marked prolapse was present, and although the piles were reduced after injection reduction was not maintained and strangulation occurred. In this class of case I now only inject one pile at a time, and insert a gauze pad into the anus with a large external pad firmly retained in position by a perineal bandage. Strangulation has not occurred in the last fifty cases of this series.

The injections were given at weekly intervals, and the average length of treatment was five weeks. The thrombosis produced extends along the veins until they perforate the coats of the rectum. In no case has embolism, peritonitis, or pyaemia occurred, such as has been described by others.

After the first visit the patients returned with great regularity, submitted themselves with every confidence that they were not going to suffer much pain, and all stated that their rectal and general condition had greatly improved after the first injection, their usual expression being, "they never felt better in their lives." Four of them had been operated on for piles, and stated that they would not now subject themselves to operative measures on account of the pain associated with them and the long time they were incapacitated after the operation. Cycling after the injection is not recommended, although one man (a furnaceman) immediately after his injection cycled four miles to his work and after work cycled the same distance home again. The progress of this case was uneventful. In some cases two to three months after the injections small "tags" were noticed where the piles had been. If these were of any size or caused any discomfort they were removed. One case, although the patient stated that he felt much better after the treatment, was rather disappointing; the piles became thrombosed but the sphincters did not regain their tone,

# British Medical Journal.

SATURDAY, NOVEMBER 3RD, 1923.

## THE SCHOOL OF HYGIENE.

DR. ANDREW BALFOUR has been appointed director of the School of Hygiene. This is the first step towards the creation of an institution which will, we hope, powerfully influence the development of scientific hygiene and preventive medicine in the British Empire, and beyond.

Dr. Balfour's record is such that our confidence in the success of the new school is strengthened. His own contributions to pure research imply an insight into the problems of the laboratory which qualify him to consider sympathetically the views of those who attach importance to that side of teaching which depends upon the stimulus of example rather than precept; his practical experience of men and things frees him from any specialist bias. We have always urged that a combination of administrative and research experience should be found in the director of a first-rate school of hygiene. We are glad that such considerations have guided the Committee in its choice.

The preliminary organization of the School of Hygiene, towards the building and equipment of which two million dollars were offered by the Rockefeller Foundation, has engaged the attention of a Transitional Executive Committee, under the chairmanship of the Minister of Health, for the past six months.

Prior to this a site had been secured in Bloomsbury by a committee appointed for this purpose, and the Government had undertaken to provide at a future date a sum of £25,000 annually for maintenance and staffing. Until the school was completed, when the Parliamentary grant would become available, the Rockefeller Trustees promised an annual grant of £5,000 for the salary and administrative expenses of a director. In our issue of October 6th we remarked upon the prolonged delay in the appointment of a director, and we now have the pleasure of congratulating the Transitional Executive Committee upon having secured a man with imagination, tact, discretion, and a wide experience of men and affairs in many lands; one who not only has a broad outlook on hygiene and a tried capacity for research, but has shown himself an eminently practical sanitarian as medical officer of health of the modern city of Khartoum from 1904 to 1913, and later as a member of the Medical Advisory Committee of the Mediterranean War Area. Dr. Balfour, it may be noted, received the C.M.G. in 1912 and the C.B. in 1918. He is fifty years of age, graduated M.B., C.M., at Edinburgh University in 1894, and, four years later, when he took the M.D., gained the gold medal for a thesis on the toxicity of dysentery with special reference to river pollution. In 1900 he received the degree of D.Sc. in Public Health (Edinburgh), having already obtained the D.P.H. Camb. in 1897. His numerous publications include a textbook (jointly with Lewis) on *Public Health and Preventive Medicine* (1902), and *War Against Tropical Disease* (1920).

Dr. Balfour, it may be noted, received the C.M.G. in 1912 and the C.B. in 1918. He is fifty years of age, graduated M.B., C.M., at Edinburgh University in 1894, and, four years later, when he took the M.D., gained the gold medal for a thesis on the toxicity of dysentery with special reference to river pollution. In 1900 he received the degree of D.Sc. in Public Health (Edinburgh), having already obtained the D.P.H. Camb. in 1897. His numerous publications include a textbook (jointly with Lewis) on *Public Health and Preventive Medicine* (1902), and *War Against Tropical Disease* (1920).

Dr. Balfour's record is such that our confidence in the success of the new school is strengthened. His own contributions to pure research imply an insight into the problems of the laboratory which qualify him to consider sympathetically the views of those who attach importance to that side of teaching which depends upon the stimulus of example rather than precept; his practical experience of men and things frees him from any specialist bias. We have always urged that a combination of administrative and research experience should be found in the director of a first-rate school of hygiene. We are glad that such considerations have guided the Committee in its choice.

The preliminary organization of the School of Hygiene, towards the building and equipment of which two million dollars were offered by the Rockefeller Foundation, has engaged the attention of a Transitional Executive Committee, under the chairmanship of the Minister of Health, for the past six months.

Prior to this a site had been secured in Bloomsbury by a committee appointed for this purpose, and the Government had undertaken to provide at a future date a sum of £25,000 annually for maintenance and staffing. Until the school was completed, when the Parliamentary grant would become available, the Rockefeller Trustees promised an annual grant of £5,000 for the salary and administrative expenses of a director. In our issue of October 6th we remarked upon the prolonged delay in the appointment of a director, and we now have the pleasure of congratulating the Transitional Executive Committee upon having secured a man with imagination, tact, discretion, and a wide experience of men and affairs in many lands; one who not only has a broad outlook on hygiene and a tried capacity for research, but has shown himself an eminently practical sanitarian as medical officer of health of the modern city of Khartoum from 1904 to 1913, and later as a member of the Medical Advisory Committee of the Mediterranean War Area. Dr. Balfour, it may be noted, received the C.M.G. in 1912 and the C.B. in 1918. Dr. Balfour's record is such that our confidence in the success of the new school is strengthened. His own contributions to pure research imply an insight into the problems of the laboratory which qualify him to consider sympathetically the views of those who attach importance to that side of teaching which depends upon the stimulus of example rather than precept; his practical experience of men and things frees him from any specialist bias. We have always urged that a combination of administrative and research experience should be found in the director of a first-rate school of hygiene. We are glad that such considerations have guided the Committee in its choice.

The preliminary organization of the School of Hygiene, towards the building and equipment of which two million dollars were offered by the Rockefeller Foundation, has engaged the attention of a Transitional Executive Committee, under the chairmanship of the Minister of Health, for the past six months.

One of the chief needs at the present time is the application of existing knowledge to local conditions, but this can only be done adequately when men are well trained in the underlying principles. There remains much room for improvement in the ordinary teaching of hygiene and the dissemination of existing knowledge both at home and abroad. The provision of sound training will be one of the great functions of the school. As it is only by considering hygiene in its historical perspective that a true notion can be got of all that has been accomplished by the world at large, and particularly by many pioneers of the work in this country, Dr. Balfour has foreshadowed the creation of a great museum of hygiene, which would not only give a graphic idea of the part played by hygiene in the economic development of the empire, but could indicate the gaps which remain in our knowledge and suggest the lines upon which the most useful practical results might be expected from research.

It is probable that a large proportion of the students in a school situated in London will be men preparing to enter the public health service of this country, and the school must therefore provide a normal course of study furnishing the technical and scientific equipment prescribed as essential by the General-Medical Council. It would be wholly wrong if students whose aspirations do not extend beyond these requirements should not find in the school what they need, but it is evidently the purpose of the Executive Committee, as it was the intention of the Rockefeller Foundation, that the new school should be essentially imperial in scope, and should become a centre to which other nations may also bring their problems for practical assistance towards their solution. But it is obvious that the endowment of £25,000 promised by the Government will be inadequate for the proper staffing and maintenance of the teaching appointments and research departments of the new institute, and that the Transitional Executive Committee must so direct its policy as to secure the inclusion under the charter of the new school of the good-will and endowments of other bodies already engaged in the same work. May it not be that here is the dawn of the coming of a great school of post-graduate medical studies in London?

A really great school is one all of whose professors are enthusiasts for their special subjects, but also broad-minded enough to recognize that no single branch of science is either self-subsiding or all-embracing, and are prepared to work loyally together under the chairmanship of a broad-minded and experienced director.

In a country such as ours, proud of ancient and famous educational establishments, a new college must struggle hard to secure any measure of popular prestige. All Englishmen are tinged with academic conservatism; it is not only the alumni of Oxford and Cambridge who respect the ancient universities more than those founded in our own time. So the task before Dr. Balfour and his future colleagues is not a light one: they do not inherit the prestige of a long series of illustrious predecessors; they have behind them no tradition—they themselves must create what shall become a tradition. Upon their singleness of purpose everything depends. The best wish we can utter is that when, in the fullness of time, Dr. Balfour comes to give an account of his directorate, he may be able to apply to himself and his coadjutors the words of Henry V., "We few, we happy few, we band of brothers."

end of the inverted bowel were inflamed and adherent, and the peritoneal sac contained a little clear fluid. The peritoneum generally, and that of the greater portion of the inverted intestine, appeared healthy. A tube having the position and relations of the vermiform appendix was thickened and distended and fixed in its whole length (two inches) by old adhesions. It was soft and its cavity communicated with that of the caecum through a narrow opening.

This dog obviously suffered from chronic appendicitis and from an intussusception which proved fatal. The conditions were exactly those which might be found in a child. I had, however, some doubts about the teaching and, on consulting *Quain's Anatomy*, I found the following: "So far as is known, the appendix is peculiar to man and certain of the higher apes, and to the wombat" (*Quain*, ninth edition, vol. ii, p. 614). Mr. Powell, the librarian of the Royal Society of Medicine, kindly looked up the authorities for me and wrote that "all the books and treatises we have state definitely that the appendix is wanting in domestic animals."

No opportunity to dissect another dog has presented itself, but a paper recently published by W. A. Costain of Toronto gives evidence that the dog has an appendix. This paper is most interesting. It records that when a ligature is placed on the appendix and the meso-appendix of a dog septic peritonitis follows and is fatal in about two days (*Surgery, Gynecology, and Obstetrics*, vol. xxxvi, p. 365). But if the thoracic duct is ligatured and drained twenty-four hours after ligaturing the appendix, the poison, instead of being taken into the blood stream, is discharged from the body and recovery takes place. A collateral lymph circulation develops, and the drainage fistula heals spontaneously. Dr. Costain tied and opened the thoracic duct, close to its entry into the vein, in the neck of a 9-year-old child suffering from acute pneumococcal peritonitis. No abdominal operation was performed except the removal by aspiration, for examination, of half a cubic centimetre of pus from the right side of the peritoneal cavity. This pus contained pneumococcus iv. Rapid disappearance of all symptoms proved that septic absorption had ended. The abnormal abdominal conditions gradually subsided, and the patient was discharged, cured, twenty days after the operation.

The extraordinary power of the peritoneum to get rid of infection is one of its most remarkable features. Nevertheless septic peritonitis is common, and when definitely established it is usually fatal. Hence a main object of surgeons during the last forty years has been the prevention of septic peritoneal infection. This has been in great measure effected by averting its causes. But still it occurs, and Dr. Costain's observations prove, as he claims, that "when a fatal absorption is overcome, the peritoneal cavity is capable of looking after such a formidable structure as a necrotic appendix." It would appear, therefore, that lymphaticostomy must be considered an important and hopeful treatment for the prevention and cure of septic peritonitis in suitable circumstances.

## A SERIES OF CASES RESEMBLING PARALYTIC ILEUS.

BY

W. W. JEUDWINE, M.D., B.Ch.,

LIEUTENANT-COLONEL I.M.S., CIVIL SURGEON, DELHI.

THE following cases have come under my treatment during the last three years, and I am publishing them not only on account of their interest but also to invite correspondence as to the cause. I can find nothing described in the various systems of surgery which in any way resembles the cases under report.

### CASE I.

In July, 1921, at Rawal Pindi Civil Hospital, a well developed young Punjabi, aged 22, came in complaining of abdominal pain and giving a history that his bowels had not been open for ten days. He did not appear to be in the least distressed and except for a distended abdomen was otherwise normal. His tongue was clean, pulse 80, temperature 98°. Pain was of a general character and no special point could be elicited on palpation. Per rectum nothing abnormal was felt.

He was admitted and given an enema with oil, soap, and turpentine. Water only by mouth. Seen the next morning, his general condition was the same. There was no sign of peritonitis. The enema had been passed almost clear. The abdomen remained distended and he complained of rather severe pain. A second enema was given and 1 1/2 c.cm. pituitrin hypodermically. He passed urine but no flatus, and the wash-out was returned clear. Seen again the following day he was in the same condition. He had not vomited, there was no rigidity, his pulse remained 80, and his temperature normal. He however complained of more severe pain, so I decided to do a laparotomy.

The operation was done that morning under chloroform. On opening the abdomen free blood-stained fluid escaped at once (I suppose in all there were two pints of free fluid), the small intestines, in large distended coils, and purple in colour, evacuated themselves and were immediately surrounded by hot saline towels. The large intestine was seen to be equally distended but not so discoloured. No line of demarcation of strangulation was seen, in fact the large intestine was distended down to the lower sigmoid. A rectal tube was passed well up the lower bowel and at the same time the small intestine was punctured by a large trocar and cannula and the contents as much as possible evacuated. Two ounces of mag. sulph. in ten ounces of water were introduced into the small intestine at the last puncture. Four punctures in all were made, three in the small and one in the large intestine. The intestines were returned fairly easily and the abdomen closed. Pituitrin 1/2 c.cm. was given four-hourly for six doses. The rectal tube was left *in situ*. The patient was kept in Fowler's position, and only sips of hot water given by the mouth. He made an uneventful recovery and left the hospital fourteen days later.

### CASE II.

At Rawal Pindi two weeks later, a frail woman, aged about 40, walked into hospital complaining of abdominal pain and giving a history of absolute constipation for fourteen days. As in the last case, except for a distended abdomen there were no signs or symptoms of disease. She was a feeble creature with a small pulse and no physical reserve. She was given an enema as in the previous case, with the same result. The next morning as she was no better I decided to do a laparotomy and the operation was done as in the previous case.

On opening the abdomen there was no free fluid, but the intestines had the same purple appearance and were greatly distended. The same routine was carried out as rapidly as possible and the abdomen closed. In spite of pituitrin, camphor in oil, nux vomica, and enemata, her bowels refused to act and she died three days later. No obstruction was found at the time of operation and at necropsy no signs of inflammation, kinks, or bands.

### CASE III.

At Jullundhar in November, 1921, an emergency case of intestinal obstruction was admitted at 5 p.m. The patient was an old, frail, wizened-up man about 60 years of age. He gave a history of absolute constipation for fourteen days, and had a distended abdomen with some abdominal pain. He had come in by road eighteen miles in an ekka and walked from it to the surgery. He was given an enema and a stimulant draught. The enema produced no result.

At 6 p.m. a laparotomy was performed. Free blood-stained fluid escaped from the abdominal cavity. The small intestine was distended, but the most curious feature was that the internal and muscular coats appeared to have given way in places and the peritoneal coat only remained intact and that was distended in large beads about the diameter of a sixpenny piece. The case was so obviously hopeless that a Paul's tube was tied in and the patient returned to the ward. He died the same night. In getting the Paul's tube out the abdomen was opened and again no visible obstruction was found.

### CASE IV.

At Delhi in January, 1923, a Pathan boy, aged about 18, was admitted with a history of nine days' constipation and a painful distended abdomen. His tongue was foul, pulse 100, temperature 99°. An enema was given without result, and he was operated on almost immediately afterwards.

At operation the same condition of the intestines was found except that the large intestine was not so distended. The only possible cause of obstruction was a slight mesenteric kink at the hepatic flexure of the large intestine, but was not sufficient to cause more than slight partial obstruction. The gut did not contract down well after evacuation of the contents by the cannula, nor did much material or gas escape by the rectal tube. In spite of all the usual remedies he never passed flatus, and died three days later.

If a complete *post-mortem* examination had been possible on these last three cases some cause might have been found to account for the condition; but what about Case I, who was apparently of the same type? I feel that I cannot be the only civil surgeon in India who has come across this type of case and should be glad to hear the experience of others.

In the first two cases I was assisted by Assistant Surgeon Gopal Dass and Sub-Assistant Surgeon Chand Narain; in the third case by Khan Sahib Mohammed Shariff; and in the last case by Lieut.-Colonel H. Hallilay, I.M.S.

**THE INSURANCE CRISIS: EMANCIPATION.**

The Minister of Health has receded from his original position, and has given explicit assurances on certain matters to which the Insurance Acts Committee attaches supreme importance, although complete satisfaction has not been obtained. Representatives of the Insurance Acts Committee saw the Minister on two occasions on October 30th; the first meeting was occupied in preliminary discussions. The declaration of the Minister, published in the *SUPPLEMENT* this week, makes two things clear. One is that medical benefit is a primary benefit, and that there is no title to additional benefits until this and the other primary benefits—sickness, disability, and maternity—are satisfied; the other is that the remuneration of practitioners is to be settled on its merits, and agreed by negotiations between the Minister and the profession.

The demand of the profession that an inquiry, by Royal Commission or otherwise, should be impartial, and comprehensive, and should embrace the whole field of the insurance scheme, including finance and the administration of approved Societies as well as medical benefit, has been accepted. The scope of such an inquiry is guaranteed by the undertaking that the exact medical profession shall be consulted as to the financial side there is also some gain. Alternative proposals are made. The offer of the Minister covering all the points which have been the subject of negotiations will be submitted to the Special Conference of representatives of Local Medical and Panel Committees which has been summoned for November 14th, and it will be for the Conference to take into consideration the specific alternative offers under the head of remuneration. These are, on the one hand, a separate and immediate inquiry into the appropriate capitation fee for 1924; or alternatively a guaranteed fee of 8s. 6d. for five years, instead of three as originally proposed. During this period of five years the wider inquiry of the Royal Commission would be proceeding. Meanwhile, in view of the statutory requirement that two months' notice must be given, the resignations of insurance practitioners were placed in the hands of the clerks of Insurance Committees throughout the country on October 31st. Whether they become operative on January 1st or are withdrawn will depend on the decisions of the Panel Conference.

Throughout the negotiations the Committee has been careful to stress the claims of rural practitioners, and it is satisfactory to find that it has succeeded in inducing the Minister to guarantee the setting aside of a sum of £250,000 for the year 1924 (as against approximately £210,000 in the present year) as an addition to remuneration.

The hands of the Insurance Acts Committee, in conducting the negotiations, have been greatly strengthened by the knowledge of the manner in which resignations have been tendered—the final result being that 94 per cent. of the insurance practitioners of Great Britain have resigned. The whole medical profession resulted in clarifying the position of every member of the profession, whether an insurance practitioner or not, in regard to State service. It has made it clear and authoritative that in relation to services rendered by unconstituted claims or pretensions on the part of any particular section of the community.

**THE MEDICAL INSURANCE AGENCY.**

A meeting of the Committee of Management of the Medical Insurance Agency was held at the house of the British Medical Association on Thursday, October 23th, when, in the absence of Dr. G. E. Haslip owing to indisposition, the chair was taken by Dr. H. A. des Voeux. Other members present were Dr. E. Wearer Adams, Lieut.-Colonel R. H. Elliot, Dr. R. A. Gibbons, Dr. R. Langdon-Down, Sir Dawson Williams, Sir Squire Sprague, and Mr. W. E. Waine. The secretary presented the audited balance sheet for the year 1922, together with the chairman's report thereon. A very interesting detailed schedule showed the great and rapid progress made by the Medical Insurance Agency during the last eight years. The premium income increased from £12,104 in 1915 to £37,836 in 1922, whilst the commissions, etc., earned rose from £1,990 in 1915 to £3,250 in 1922. For the third year in succession policies totalling over £100,000 in sums assured in respect of life and endowment assurance were arranged through the medium of the agency, bringing the total sums assured up to December 31st, 1922, under these heads to over £700,000. Business in fire and accident insurances has increased; the convenience of paying one premium for all household risks under a flat rate is apparently much appreciated. An interim report by the Chairman for the nine months ended September 30th, 1923, stated that the popularity of this comprehensive household contract continued. In spite of a decline in life assurance business experienced by all offices, and in spite of the existence of keen competition, the agency negotiated 66 new life policies during the period. One of the advantages—and not the least—of the Medical Insurance Agency is that members of the profession can obtain from it personal advice as to the particular kind of policy to meet the individual's particular needs. During the Annual Meeting at Portsmouth no fewer than fifty-five interviews looking at peculiar matters to the satisfaction of the applicant. The amount of business in insuring motor cars done by the Agency increased during this year, but bearing in mind the large number of cars now used by members of the profession it is believed that the amount could be considerably increased. Motor car insurance is a specialized business; accidents are more heavy and frequent than in almost any other form of insurance, and members of the profession would be well advised to take advantage of the security offered them to obtain fair and equitable settlements by insuring through an Agency. The Committee has for some time felt that the benefits already conferred upon the profession might be increased were it in a position to obtain for the person insuring through it advice on all matters affecting the purchase and use of motor cars. An arrangement has now been made with the firm of Mann, Egerton, and Co., Ltd., to advise members free of charge, either directly or through the medium of the Agency, on any problem, difficulties, disputes, or technical matters relating to motor cars, including motor coachwork and accessories; to give advice as to the suitability of any particular car for any class of work or type of district; to undertake the periodical inspection of members' cars at a moderate fee; to give expert advice as to the mechanical condition of members' cars, and the advisability of repairs, and to prepare specifications and estimates for repairs to mechanical or coachwork, or for the manufacture of special bodies to meet particular requirements, and generally to place their entire resources at the disposal of members, both in London and throughout the country. The firm has been established over twenty-five years; it possesses experience, a staff of experts, and large works at Ipswich, Norwich, and in London (156, New Bond Street, and 14, High Road).

animals and plants—of specific kinships underlying superficial differences, and of disorders of the more complex animals by the light of elementary changes in the simplest animals and in plants, in which the plasticity, I had almost said the pregnancy, of protoplasm shows us in manifold ways its marvellous endowments."

The President referred to the work of Pasteur and John Hunter, both of whom used the comparative method of study with conspicuous success, and closed his remarks by quoting Benjamin Franklin's now proverbial phrase, "Hard work is still the road to prosperity, and there is no other."

Professor HODDAY read a paper on cryptorchidism in animals, and illustrated his communication with a series of lantern slides, photographs, and drawings of testes retained in the abdomen or inguinal canal of animals.

Mr. McADAM ECCLES followed with a paper on imperfectly migrated testis in man, and dealt with the etiology, function, morbid anatomy, and treatment of this condition. He dismissed any possible influence of the endocrine glands, which have such a profound effect on the formation of secondary sexual characteristics, for these act everywhere through the blood stream, and presumably would act equally in the one testis which has remained within the abdomen and the other which has migrated to the scrotum. The factor of heredity, so important in animals, appeared to be less common in man, for in answer to his inquiries not more than 2 per cent. gave a history of like condition in grandfather, father, or brothers. It was doubtful if an arrested testis was ever fully developed. Cases were on record in which a man with double abdominal retention of testes had procreated children and most abdominal testes had the power of producing an internal secretion, but perhaps not of the same type as that of a fully developed and fully migrated organ. A testis within the abdomen was liable to all the diseases to which a fully migrated testis was prone—for example, inflammation, cysts, neoplasms, and serotal hydroceles and herniae might be associated with completely retained testes. In discussing treatment Mr. McAdam Eccles pointed out that inflammation or enlargement of an abdominal testis called for its prompt removal, but simple unilateral or bilateral abdominal retention required no surgical interference. The removal of a pair of abdominal testes would, of course, deprive the body of organs which might provide some internal secretion.

To the subsequent discussion on these two papers Sir JOHN BLAND-SUTTON added his experience of the pathology of this disease and indicated useful fields for further research; a number of veterinary surgeons also contributed to the debate.

## THE ENDOCRINES AND THE WORK OF THE KIDNEY.

IN his presidential address to the Section of Urology of the Royal Society of Medicine on October 25th, Dr. W. LANGDON BROWN dealt with the relation of the endocrines to the work of the kidney.

He said that the primitive excretory organs as found in invertebrates were nephridia, typical segmental organs opening internally into the body cavity and externally on to the surface. On Gaskell's theory of the origin of the vertebrates from arthropods, the old alimentary tract, of which the infundibulum represented the mouth, became the central canal of the nervous system. In the crustacea the gills kept up a vigorous current of water from behind forwards so that waste products which were discharged in this situation were speedily carried away from the animal, whereas in the fish, with the current going in the reverse direction, this would have led to contamination of the water supply to the gills. Circumstances brought about an alteration in function, and a new use was found for the gland in this position: it became the pituitary. Comparative morphology pointed to the conclusion that, in the neighbourhood of the gill slits, segmentally arranged structures gave rise to the tonsils, thyroid, parathyroids, and thymus, in positions which might be expected if they were homologous with nephridia. It might be asked why the excretory functions, originally so uniformly distributed in segmental nephridia, had become restricted to such con-

denser structures as the kidneys. It was doubtful whether the tubules of the vertebrate kidney were strictly homologous with the nephridia of invertebrates, although they were so similar in structure and function. Nephridia arose as invaginations from the exterior, and were therefore epiblastic, and in the lower vertebrates the kidney tubules grew out from the body cavity, and were therefore mesoblastic.

There seemed to be three interesting phases in the evolution of the excretory system: (1) the epiblastic intercellular nephridia of the invertebrates which opened into the body cavity; (2) the mesoblastic intercellular kidney tubules of the lower vertebrates shut off from the body cavity; (3) a return in the higher vertebrates to the process of epiblastic invagination, but not to an intracellular duct nor to a communication with the body cavity. The opinion of biologists at the present time was in favour of this view. It was an extraordinary example of the way in which Nature could change her plans according to circumstances and construct organs *de novo* which resembled the old ones closely enough to have deceived biologists for more than a generation. It showed how plastic the evolutionary process was, and that it was not so dependent upon recapitulation as was thought. He went on to suggest that the influence of the endocrine system on the kidney was, in part at least, an expression of the interest it continued to take, as it were, in functions formerly its own. When nephridia were replaced by the more adaptable mechanism, and some of their outlets were dammed up by the formation of new structures such as the vertebrate alimentary tract and the pleural folds, they had either to vanish altogether or to take on some new function. To a large extent the second course was adopted, and some of them became endocrine glands. The internal secretions might be looked upon as specializations of the old chemiotactic mechanisms, and they revealed their antiquity in the way they clung to the vestigial structures. Not infrequently when, in the course of evolution, a structure had become useless for its original purpose the endocrine system supplied it with a new tenant. This change of function was illustrated by the adrenal cortex, the thyroid, thymus, pituitary, and pineal glands, all of them, except the last, structures representing modified nephridia, and he doubted whether the pineal was properly an endocrine structure at all. Not only were there vestiges of excretory structures in the endocrine glands, but there were vestiges of excretory methods in the internal secretions, as he proceeded to illustrate. In short, the particular function of the primitive nephridia was to bring the internal working of the organism into harmony with its environment, and this was exactly what the endocrine system continued to do, both through its secretory activity and its close association with the sympathetic nervous system. The kidney was thus set free from the labour of forming an internal secretion, and able to devote itself entirely to excretion, while at the same time its work was influenced by the other internal secretions so as to ensure a harmony between the internal economy and its environment. This was of biological interest, because in the pituitary they had a gland which was definitely excretory in function in invertebrates as high as the crustacea; and it was of clinical interest also as bearing on diabetes insipidus and polyuria in general. He went on to discuss the pathology of diabetes insipidus from this point of view, agreeing with Rabinowitch in regarding diabetes insipidus as being due to the lack of some internal secretion which normally regulated and moderated diuresis by acting upon the cells of the kidney. He looked upon pituitrin as that secretion, and it seemed to him that the situation could be expressed most conveniently by saying that the output of the pituitary regulated the threshold of the kidney for water. This would account for the apparently aberrant instances of a diuretic effect of pituitrin, and would also explain how, while having a selective action on water, it did not hinder the output, for instance, of dyes. The material excreted by the kidney fell into two categories: purely waste products, useless to cellular life, for the excretion of which there was no threshold, and products which might play a useful part in cellular life—sugar, sodium chloride, haemoglobin, and water—in the way of which the kidney did interpose a threshold, so that they only passed into the urine when their level

developed towards each side, where it was closely related in front to the anterior layers of the levator ani and behind to the parametric tissue.

He considered that the sphincters were the most important factors, and in support of this contention he cited the fact that incontinence of urine was not commonly met with in cases of prolapse, even when the anterior wall, and presumably the supporting structures of the bladder, were much weakened and displaced. He described the more important operations for the cure of this condition, and illustrated his descriptions by lantern slides.

The operation which he performed in his most successful cases was as follows:

The perineum was first incised to allow of easier access to the parts. A triangular area of the anterior vaginal wall was removed, exposing the urethra and bladder. A mushroom catheter was then passed into the bladder, and, using this as a guide, two mattress sutures of catgut were inserted into the tissues on each side of the bladder neck (after Kelly). Deep sutures were then inserted through the para-urethral tissues to narrow the canal throughout its length, and the anterior colporrhaphy then completed in two layers. Finally the perineal incision was sutured.

#### Notes on Two Cases.

*Case 1.*—An unmarried woman, aged 26 years, had a normal menstrual history. She was a thin, poorly nourished woman, with very little energy and very depressed and miserable. She had suffered from urinary incontinence practically since birth, being troubled during the day, but worse at night. She had tried all sorts of medical treatment. On examination, the external genitals were normal and of virginal type; the vaginal orifice admitted one finger with difficulty, but the upper part of the anterior vaginal wall appeared somewhat lax, although there was no actual prolapse; the uterus was normal in size and acutely anteverted. After the operation, as above, she required catheterization for a week. Her bed was wet once before she was discharged from hospital. She had been well ever since then—two and a half years ago—and was now a cheerful, healthy-looking young woman.

*Case 2.*—An unmarried young woman, aged 21 years, had a normal menstrual history. She was rather thin and miserable, and not very bright mentally. She was apparently normal until an acute illness ten years ago, but since then had been incontinent, chiefly at night, but also during the day. For the last six years she had not had a holiday owing to her bed-wetting. On examination, the external genitals were normal; the vaginal orifice was virginal, and again a considerable laxity of the upper part of the anterior vaginal wall was found; the uterus was normal in size and acutely anteverted. It was now over six months since her operation and she had wetted the bed twice since; but she had been away for a holiday and was much better in every way.

The great majority of these cases of incontinence could be cured, or at any rate much relieved, by operative treatment. There was no doubt that many young single women were allowed to go on suffering from this distressing ailment because no obvious lesion could be made out, and the disability was attributed to neurosis. There was a neurotic element, no doubt, but the real underlying cause would be found to be in a weakness of the sphincter mechanism, which could often be dealt with successfully by surgical methods.

In the discussion which followed, Dr. MILES PHILLIPS said he thought that incontinence of urine was a common feature of partial vaginal prolapse in multiparae. The PRESIDENT expressed surprise at the high figure (8 per cent.) of incontinence in nulliparae. He did not believe that incontinence was due to neurosis. There was not a single structure in the apparatus which could be said to constitute a true sphincter. Dr. W. E. FOTHERGILL said that he had done Pawlik's operation a few times with success. He questioned whether incontinence of urine was common in cases of vaginal prolapse in multiparae. He thought that the operative measures taken were a suggestive treatment. Dr. LEITH MURRAY said that the fact that the incontinence was worse at night pointed to the neurotic element rather than to the dislocation theory.

#### Cases and Specimens.

Dr. J. H. WILLETT (Liverpool) showed a specimen of sarcoma of the uterus, which was removed from a nulliparous woman, who had been married for six months; the condition was diagnosed as a cystic adenoma of the ovary with a fibroid in the uterus. At operation the cyst was tapped and blood-stained fluid evacuated; only then did the origin of the tumour become apparent. The specimen consisted of a partly cystic, partly solid mass arising from the fundus of a slightly enlarged uterus, in which was a small fibroid nodule. Sections of both showed the appearance of a mixed-celled

sarcoma. Three months after operation the patient looked well and had gained 17 lb., although portions of capsule of growth had been left adherent to intestines. Dr. DONALD requested Dr. Willett to report on the case in twelve months' time to inform the society if the patient was without recurrence.

Dr. H. LEITH MURRAY (Liverpool) showed sections of a squamous-celled carcinoma of the cervix from a nullipara, aged 27 years; she had been married for two and a half years. There had been bleeding and discharge for seven months, and loss of weight. The cervix was thickened and ulcerated, and the growth had invaded the broad ligaments and uterosacral ligaments and was quite inoperable.

Dr. LEITH MURRAY also described a case of colloid carcinoma of the uterus in a 2-para aged 28. She had complained of pain in the bowels for six months; there was no blood-stained discharge, no urinary trouble, and no loss of weight.

On examination, there was a large mass in the abdomen extending nearly up to the umbilicus, and distending the anterior abdominal wall. Above this was a movable mass the size of a fist. On vaginal examination, the cervix was found so greatly enlarged as to fill the vagina up to the ostium vaginae, and to prevent insertion of the finger between it and vaginal walls. The cervix was ulcerated, was continuous with the abdominal mass, and was absolutely fixed. Sections of pieces of cervix showed a typical colloid carcinoma with normal cervical glands scattered throughout, in some places greatly compressed. The diagnosis was malignant disease of the ovaries with colloid cancer of the uterus, and secondary omental deposit. This was confirmed by laparotomy, and a portion of omental growth was removed which showed on section the typical colloid appearance. The patient died six weeks after operation. The origin of the colloid growth was obscure owing to the presence of normal cervical glands in all sections, in spite of so great an enlargement of the cervix.

Dr. J. E. GEMMELL (Liverpool) read notes of two cases of fibroid tumours associated with gestation.

*Case 1.*—A 5-para had a fibroid, undergoing red degeneration, growing from the fundus uteri, which was detected in the early stage of pregnancy, and gave rise to no symptoms or discomfort during gestation; the case ended in normal labour. The fibroid was of such a size that its weight was 4 lb. 3 oz. During the puerperium, pain and pyrexia were marked, the accompanying toxæmia determining operative treatment by hysterectomy. Intermittent pains, commencing twenty-four hours before operation, had resulted in dilatation of cervix and expression of a large part of the growth filling the vagina. The tumour was a typical example of red degeneration, with necrosis.

*Case 2.*—A 2-para with a history of three months' amenorrhoea and recent slight blood-stained discharge, had a fibroid, the size of a tennis ball, situated posteriorly and filling the pouch of Douglas; double ovarian cysts were also present, and the whole of the pelvic organs were matted in the pelvis, forming a fixed mass. Pan-hysterectomy and double ovariectomy were performed. The cysts proved to be "cystadenoma."

#### MODERN METHODS OF ANAESTHESIA.

At the meeting of the Aberdeen Medico-Chirurgical Society on October 25th, the President, Dr. ALEXANDER OGSTON, delivered his presidential address on some modern methods of anaesthesia. He first gave a brief survey of the methods of anaesthesia in common use in Aberdeen within his own experience, pointing out that down to about 1917 the method in practically universal use was the administration of chloroform, or in rare cases ether given in a cone-shaped towel. As long ago as the early eighties of last century Dr. Blaikie Smith, however, had devised and used with a certain amount of success a special inhaler of leather and metal with flannel padding for the administration of open ether. About 1917 open ether came into more common use, having been brought to the notice of anaesthetists by Sir Henry Gray after a visit to America. Dr. Ogston then discussed this method, indicating its difficulties, and describing the various methods in use and the types of apparatus, including his own special mask, which prevented the diffusion of the ether vapour. The intratracheal and rectal methods were specially referred to. The use of combined nitrous oxide and oxygen was then discussed, and apparatus shown; modern improvements were indicated and the use of this anaesthetic with the addition of ether or of chloroform and ether described. On the motion of Dr. THOMAS FRASER, C.B.E., D.S.O., the President was accorded the thanks of the meeting for his valuable address.

from the competing dairy farms. In addition to giving in tabular form the detailed results of the various examinations, the pamphlet contains some reports giving information of more general interest. The practice by the county medical officer of health emphasizes the value of such commissions in securing greater cleanliness of milk and production, and in reassuring the public in this respect. The report of the surprise inspections of the various farms by the inspecting judge includes several details of practical value with reference to the cleanliness and construction of cowsheds, milkrooms, and utensils; notes on the methods of milking, protection of milk from contamination, cooling of products, and the important matter of cleansing the cows before the milking operation. Where second visits were possible it was noticed that considerable improvements had followed criticisms made on the occasion of the first inspection, and it was manifest that the competition was inducing a keener interest and an increasing carefulness in more than one direction. The report of the bacteriological examinations (six samples of milk from each competitor, in addition to "surprise samples") contains further evidence that the sterilization of utensils was being more effectively performed in consequence of the educative influence of the competition. The winner of the competition contributes a report, "How I produce clean milk," and an article by the assistant county medical officer of health on the care of milk in the home contains many practical hints which should be widely disseminated, especially during the summer months. The whole pamphlet is particularly interesting, and it deserves consideration by the general public outside the county of Kent. It is to be hoped that such competitions will multiply throughout the country; their practical value is evident, and they are very highly approved by the Ministry of Agriculture. The address of the society is 22, High Street, Maidstone.

Various papers have been written on the problem of estimating the energetic requirements of muscular work. Cathcart and Orr (1919) used the Haldane-Douglas method, for which the respiratory quotient has to be calculated for each experiment. Waller attempted to simplify this by determining the respiratory metabolism from a knowledge of the carbon dioxide only. His results were founded on a large number of professional men, dock laborers, and persons occupied in other industries. His method has, however, been adversely criticized by several physiologists. Greenwood and Newbold have recently discussed the whole subject from the statistical point of view, and have shown arithmetically some of the difficulties involved. The data based on 483 observations on a trained subject, lying, sitting at rest, and working. From the analysis of the data as a whole they found that the mean of the respiratory quotient almost agreed with that adopted by Waller, but that the variability of oxygen use was too large for it to be possible, from knowledge of the output of  $\text{CO}_2$ , to predict at all accurately the oxygen use. Even when the subject was at rest (lying on a couch) the variation was large, of the order of 8 per cent. of the mean. Similarly, when work experiments were considered, it was found that if four variables— $\text{CO}_2$ , work per minute, speed of work performance, and total previous work—were all known, the oxygen use had a variability of nearly 7 per cent. The paper deals also with the estimation of external work when the respiratory metabolism is known, or with the converse problem of estimating the

#### RESPIRATORY METABOLISM.

metabolism from a knowledge of the work performed. In work was 14 per cent. of its mean, and a knowledge of oxygen use too did not sensibly reduce the variability. Given also knowledge of the speed with which work was performed, the variability was only reduced to 11 per cent. An attempt to improve the prediction of work was made by reducing the range of work to the range in the whole series of experiments being large; but the variability in this was of the same order as in the previous analysis. No better results were obtained in estimating the respiratory metabolism from a knowledge of the external work. The variability of both oxygen use and  $\text{CO}_2$  output was of the order of 12 per cent. These results are all based on carefully made experiments on a single individual. It follows that in any practical application of this method, where many individuals are involved, the variation would be still larger and consequently the predictions still less exact. The authors conclude that "when any expert-mental calibration of different forms of muscular work is based upon the constancy of small samples of measurements upon different subjects, only the roughest results are attainable."

The London Gazette of October 26th announces that the King has appointed Sir Humphry Davy Rolleston, K.C.B., to be Physician in Ordinary to His Majesty in the room of Sir James Reid, Bt., G.C.V.O., K.C.B., deceased, and Dr. Edward Farghah Buzzard to be Physician Extraordinary to His Majesty.

Mr. Walter C. Spencer's Bradshaw Lecture before the Royal College of Surgeons of England will be given at the College on Thursday next at 5 p.m. Members of the profession and students interested are invited to attend. The subject of the lecture is melanin, melanoma, and melanotic cancer.

The Columbia University Press, New York, has just published as a pamphlet the Chandler Lecture delivered before the Columbia University of New York in 1921. Like everything Professor Gowland Hopkins does it is concise, well thought out, and clearly expressed. We have so recently published his Cameron Prize Lectures that we may be excused from giving any detailed review of his Chandler Lecture. After its delivery Professor Hopkins was presented with the Chandler Medal, which is awarded yearly to a distinguished chemist. The pamphlet, which is to be obtained in this country from Mr. Humphrey Milford (1s. 6d. net), is illustrated by a characteristic portrait of Professor Hopkins.

It is referring last week to the portrait of Sir Charles Scarborough presented to the Royal College of Physicians of London by Dr. Innes Smith of Sheffield, we inadvertently spoke of the Temple Newsome picture as a replica of that at Barber's Hall. The two are quite distinct, as can easily be seen from the reproduction in Peel Ritchie's *The Early Days of the Royal College of Physicians, Edinburgh*, to which Dr. Innes Smith has called our attention. The Temple Newsome portrait is of a middle-aged man, and was painted probably when Scarborough was about 50. The Barber Company's picture shows Scarborough at the age of about 26 lecturing on a body which Edward Artis is dissecting. Youngs' *Annals of the Barber-Surgeons* gives the following minute: "Paid to Greenboure for Painting the Picture of Mr. Edward Artis and Doctor Charles Scarborough & Anathomy—£9-10-0." The Temple Newsome portrait is probably by a Dutch artist.

Greenwood and Newbold: On the estimation of metabolism from determinations of carbon dioxide production and the estimation of external work from the respiratory metabolism, *Journal of Hygiene*, August, 1923, vol. xxi, No. 4.

of inanition on growth and its sociological relations are discussed. The book is a storehouse of facts clearly and systematically arranged, and can hardly fail to become a standard work on the subject.

### PHYSICAL CHEMISTRY IN INTERNAL MEDICINE.

In his book on physical chemistry in internal medicine<sup>3</sup> Professor H. SCHADE has made an ambitious attempt to bring into closer relation the assured results of recent physico-chemical research and the practical sphere of pathology and therapy. Considering the mass of such data scattered through the literature of medical science, the time is held to be ripe for the comprehensive experiment of undertaking the definition of the contribution which physical chemistry has to make to practical medicine.

The book is divided into three parts. The first comprises a somewhat cursory statement of the fundamental properties of crystalloidal and of colloidal solutions, particular emphasis being laid on the conditions governing the stability of the latter. As a judicial statement of the physiological potentialities of modern physico-chemical thought this section loses in authority when certain important omissions have to be recorded. One finds, for example, no reference to the Donnan theory of membrane equilibrium, a theory whose application to the problems of the living cell is full of promise. A discussion of the views of Loeb on the colloidal behaviour of proteins might, likewise, have been included with advantage.

The second part is devoted to a systematic study of the progress made in the different fields of medicine under the influence of physico-chemical experiment. The problems of general pathology, infectious diseases, diseases of the blood, of metabolism, of the intestinal tract, the liver, the kidney, the vascular system, connective tissue, the lungs, the muscular system and the nervous system are dealt with in successive chapters. It will be seen that the scope is comprehensive. The author draws largely on the work of Michaelis on hydrogen ion concentration, of v. Korányi on cryoscopy, and of Höber on the physico-chemistry of the cell. A. V. Hill's remarkable interpretation of the physiology of muscle contraction is an unexplained omission.

A description of the technique of the chief physico-chemical methods of value in medical diagnosis and research makes up the third part of this book, which undoubtedly fills a gap in medical literature. Though a discrimination between fact and hypothesis is sometimes lacking, the book will not be found wanting in interest and stimulus to those medical men who are keen to bring the ward into closer touch with the laboratory. Of the fifteen hundred references quoted 95 per cent. are to work published in the author's own tongue!

### AFTER-TREATMENT OF WOUNDS AND INJURIES.

THE book on physical therapeutics<sup>4</sup> by Drs. GUILLEMINOT, DAUSSET, and DUREY is the seventh of a series of eight volumes which includes works on the special treatment of the sequelae of wounds and injuries viewed from various standpoints. The volume before us is confined to consideration of the treatment of the sequelae of wounds and of industrial accidents.

Dr. Guilleminot's chapters on electro-diagnosis are clear and informative. The various apparatus appropriate for electro-diagnosis and treatment, including that by x rays, is clearly described. He discusses adequately the quantitative and qualitative changes in the conductivity and excitability of nerves and nerve centres after injury and the best electric methods of treating these disabilities. The descriptions of instruments are clear and sufficiently full, and include those for x-ray therapeutics and also for radium therapeutics. This section is of considerable practical value.

Dr. Durey, in the introduction to the section on kinesi-therapy and functional re-education, says that despite the experiences of the war little change has been made in the essential principles; manual is, he considers, to be preferred to mechanical treatment, and above all it is to be borne in mind that the suggestive value of physio-therapeutics is very important. This section is not equal in value to the first. Passive movements are very inadequately described, while the subject of active movements is dismissed in fifteen lines of print. The pages devoted to the after-treatment of lesions of the bones, joints, and nerves are, however, of value.

The third author, Dr. Dausset, adequately presents the current practice in treatment by heat, light, and hot and cold water, and compares the advantages of various French spas.

### A TEXTBOOK OF HISTOLOGY.

In *A Manual of Histology*<sup>5</sup> by Professor V. H. MORTHAM the main departure from the conventional method of teaching this subject is to be found in the form of illustration adopted. The author considers that pencil diagrams represent to the student the pictures presented by the microscope more satisfactorily than the mixture of photomicrographs, coloured plates, and diagrams which are to be found in most textbooks. The illustrations of this book, which are all reproductions of the author's own drawings, are certainly lucid and well drawn, but it may be doubted if they possess the advantage claimed for them—in the interpretation, for example, of stained preparations. It is to be feared rather that because they are excellent examples of what the student ought to draw himself they will tempt the latter to reproduce in his notebook the diagrams themselves instead of giving a pencil interpretation of the structures revealed by the microscope.

The descriptive matter of the manual is clear and concise, the method of tabulation being much resorted to. Here again, whilst there are obvious advantages to the busy student in this method, there is a danger of short-cutting the education of the deductive powers which should surely be the main purpose of histological instruction. We note a misprint on page 85, where the ratio of red to white corpuscles in the blood is given as 50 to 1!

The book has been written for medical students and its scope is, naturally, that required for the intermediate medical examination. The first and the final chapters are devoted respectively to brief instructions in the handling of the microscope and the technique of staining and mounting sections.

The manual will be welcomed by student and teacher alike, for it will economize the labours of both. We hope that it will not result in a wholesale reproduction in our medical schools of what the author saw by the aid of his microscope.

### DENTAL ANATOMY AND PHYSIOLOGY.

In the preface to their *Textbook of Dental Anatomy and Physiology*<sup>6</sup> Mr. HUMPHREYS and Mr. WELLINGS tell us they have written a small, condensed textbook, which is intended to meet the requirements of dental students preparing for their examinations, and is based on the curricula of the various licensing bodies. This effort at condensation may be responsible for the fact that there is in the book no reference to physiology. We suggest that the process might be carried one step further by omitting all reference to physiology in the title. We should then have a very useful book on dental anatomy. The first half is devoted almost entirely to man and deals with the development of the jaws and teeth, the anatomy of the teeth, the structure and development of the tissues of the teeth, together with a short account of the temporo-mandibular articulation. Condensation has been carried to just the right point, and the chapter on the development of the jaws may be singled out for

wiped from France, "Florest Dawson's Guiltless." The following note had also been received:

"As a veteran of the staff and a former Assistant Editor and colleague of my old friend, Sir Dawson Williams, from over forty years since, I beg to tender him my hearty good wishes on this auspicious occasion, deeply regretting that age and growing infirmities have completely prevented me from being present."

ALAN DRAKE."

Sir JOHN BLAND-SUTTON said that he considered it a privilege to be allowed to propose the toast of his old friend the chief guest. Surely more than forty years of friendship was a sufficient title for him to do so. He made Dawson Williams's acquaintance many years ago, but, of course, as one got older, although one remembered things, they all seemed that, like the image in a kaleidoscope, and it was a little difficult to put them in the proper perspective. Everything that he remembered about the chief guest, however, stood out in the boldest relief. He knew logical Gardens, making post-mortem researches on animals. Dawson Williams impressed upon him the need for having his cases carefully reported, as the work was new; and later, in his quiet and unobtrusive way, initiated him into the art of dropping the ego and using the editorial "we." But slowly Dawson Williams slipped away to gain the hill-tops of journalism, while the speaker had to grovel for a living in the valleys and debiles of the abdomen. (Laughter.) He could not imagine a better Editor for such a journal as the *British Medical Journal*. Look at his record. He was a distinguished graduate of London University; he soon became physician to a hospital; he used to work very hard at the different scientific societies and became familiar and friendly with all the rising physicians and surgeons of his own time, and these had remained his friends. In addition, he was thoroughly familiar not only with hospital but with private practice. The Journal stood to-day under his management in this important position that it fulfilled its function as the official organ of the Association, and its Editor had been clever enough, while looking after the interests of the rank and file of the profession, to keep the scientific side of the art properly illuminated. He had done that by virtue of the fact that he knew all the rising young men of his day, and he had the knack of getting the right man to do the right thing. The British Medical Association throughout the Empire must be very proud of that fine *Journal*, and full of gratitude to its Editor for the wonderful way in which he had kept it in such a splendid condition both from the scientific and the general and domestic point of view. (Applause.) Editors, like surgeons, varied in ability, in temper, and in judgement, and as he had never before had the task of proposing the health of an editor he would like to refer to his qualifications and his trials. An editor must be a man with a wide knowledge of English literature, a sense of humour, and, above all things, a skill in psychology. In short, he must be patient and tolerant too. Then he had to think of his contributors and his subscribers. He must have a keen sense of proportion and space; probably in an author's contributions and his subscribers. He must have a keen sense of proportion and space; probably in an author's contributions and his subscribers. He must have a keen sense of proportion and space; probably in an author's contributions and his subscribers.

Chairman of Council, of the Council itself, and of his

sense of proportion and space; probably in an author's

contributions and his subscribers. He must have a keen

sense of proportion and space; probably in an author's

contributions and his subscribers. He must have a keen

sense of proportion and space; probably in an author's

contributions and his subscribers. He must have a keen

contributions and his subscribers. He must have a keen

sense of proportion and space; probably in an author's

contributions and his subscribers. He must have a keen

sense of proportion and space; probably in an author's

contributions and his subscribers. He must have a keen

sense of proportion and space; probably in an author's

contributions and his subscribers. He must have a keen

sense of proportion and space; probably in an author's

that occasion. In particular he thanked Sir John Bland-

Sutton—who they all hoped would long illustrate the

secret of perpetual youth—for the delightful way in which

as he thought, an excellent maxim that nothing should be

said about the dead unless it was something good. That

evening he seemed to have had the privilege—unusual, but

not unprecedented—of listening to his own obituary notice.

As he had reminded them, the speaker first became

acquainted with Sir John Bland-Sutton at the Pathological

Society, to which he brought pieces from the bodies of

animals in the Zoological Gardens, where he was prospector.

The Society was greatly interested, but, rather to his own

relief (he was reporting the proceedings), the specimens did

not lead to much discussion, the reason being that

nobody except Bland-Sutton knew anything about them.

(Laughter.) They were in fact assisting at the foundation

of a new science or a very distinct department of science—

the science of comparative pathology—which in recent days

was making very great progress. There was some hope at

that time that Bland-Sutton would devote himself entirely

to science, but he elected to be a surgeon, preferring to deal

with the living rather than the dead. Why he did not

become a physician he did not know. The distinction

between a physician and a surgeon was given to him the

other day by a lady who said, "The physician gives you

something to take in you; the surgeon takes something

out of you." (Laughter.)

His own connection with the *British Medical Journal* went

back for a considerable number of years beyond the date on

which he was appointed Editor. He was associated in the

first place with the then Editor, Mr. Ernest Hart, a very

distinguished official of the Association, and the quickest

witted man he ever knew, who was aware of what the other

person was going to say some seconds before that person

knelt at the *Lancet*, where he was in the succession from

Thomas Wakley, a person of extraordinary energy and

ability, who began life by sowing wild oats with both hands,

his journal following his example, but who eventually settled

down and obtained that certificate of respectability which

election to Parliament conferred, while the journal which

he founded and directed for many years also settled down

and became a most respectable and influential organ of

public opinion whose centenary they had the happiness

for a time had not bothered much about its constitution.

approaching its centenary, had begun in a small way, and

was now difficult to understand. The Association, now

was now difficult to understand. The Association, now

## NOTES ON BOOKS.

THE twenty-second edition of *Gray's Anatomy*<sup>9</sup> does not differ very greatly from the twenty-first, which was published in 1920. This classical work is still edited by Professor ROBERT HOWDEN, of the University of Durham; the notes on applied anatomy have been revised by Mr. John Clay, surgeon to the Royal Victoria Infirmary, Newcastle-upon-Tyne, and Dr. James D. Lickley, physician to the Children's Hospital, Newcastle-upon-Tyne. Professor Howden acknowledges his indebtedness to Professor Edward Fawcett, of the University of Bristol, who has revised the description of the development of the skull, and to Professor David Burns, of the department of physiology of the University of Durham, who revised the histological part of the book. With the disappearance from the title-page of this edition of the name of Dr. A. J. Jex-Blake (who revised the notes on applied anatomy in the previous edition) apparently the last association between *Gray's Anatomy* and St. George's Hospital has been severed. The first edition was published in 1858, when Henry Gray, then lecturer on anatomy at St. George's Hospital, was aged 31. He published the second edition in 1860, but in 1861, while he was a candidate for the post of assistant surgeon to the hospital, he died of small-pox, at the early age of 34. Between 1863 and 1880 eight successive editions were edited by Mr. Timothy Holmes, of St. George's Hospital, and between 1883 and 1887 five editions were edited by Mr. Pickering Pick, also of St. George's Hospital. Mr. Pickering Pick was assisted in the editing of the next two editions by Dr. Howden, and from 1909—the seventeenth edition—up to the present Professor Howden has been the sole editor. The new edition is only twelve pages larger than the last, but some sixty new illustrations have been added. It is unnecessary to speak of the merits of a work with which all English-speaking medical students and practitioners are very well acquainted, and the volume is as excellently produced as ever.

Potter's *Cyclopaedia of Botanical Drugs and Preparations*,<sup>9</sup> by Messrs. R. C. WREN and E. M. HOLMES, gives an account of all the plants used in botanical or herbalist practice. Only those are mentioned for which there is sufficient demand to give them a commercial value, yet about 3,000 are described. The list includes most of the plants mentioned in the *British Pharmacopoeia* and a host of others which have long since disappeared from official medicine. The herbal name, botanical name, and synonyms of each plant are given, together with a synopsis of the therapeutic action attributed to it, a list of its preparations, and a short description of its distinctive characters. In the case of British plants a line illustration is added. The book gives a large amount of quaint information about the marvellous properties of all kinds of plants which do not appear in ordinary pharmacopoeias. For example, we are told that masterwort (*Imperatoria ostruthium*) is a stimulant, antispasmodic, and carminative, and beneficial in cases of asthma, apoplexy, menstrual disorders, flatulence, and dyspepsia. To many of the official remedies unusual properties are attributed; for example, ergot is recommended for leucorrhoea, dysmenorrhoea, amenorrhoea, spermatorrhoea, gonorrhoea, and enlarged prostate, in addition to its ordinary action as a uterine stimulant. The volume is a very curious link with the past, for it may claim to be a legitimate modern descendant of the herbals of the seventeenth century. "Anything green that grew out of the mould was a wonderful herb to our fathers of old."

The nineteenth volume of the *Ophthalmic Year Book*<sup>10</sup> reverts this year to its original form. This invaluable publication was begun, it will be remembered, in 1903; in 1918 it was merged with other publications in the *American Journal of Ophthalmology*, and vols. xv, xvi, xvii, and xviii were issued in quarterly parts and named *Ophthalmic Literature*. The return to its original form will be appreciated by all; the present volume contains the references in current literature down to December, 1922; that part which deals with comparative ophthalmology contains the references to the subject since 1916. We are confident that no ophthalmic surgeon can afford to be without this excellent work of reference.

<sup>9</sup> *Anatomy: Descriptive and Applied*. By Henry Gray, F.R.S., F.R.C.S. Twenty-second edition. Edited by Robert Howden, M.A., M.B., D.Sc. London: Longmans, Green, and Co. 1923. (Roy. 8vo, pp. xiv+1373; 1,255 figures. 42s. net.)

<sup>9</sup> *Potter's Cyclopaedia of Botanical Drugs and Preparations*. By R. C. Wren, F.L.S., with additions by E. M. Holmes, F.L.S. Third edition. London: Potter and Clarke, Ltd. 1923. (Cr. 8vo, pp. xliii+392; illustrated. 5s. net.)

<sup>10</sup> *The Ophthalmic Year Book*. Vol. xix. Edited by Edward Jackson and William H. Crisp. Chicago: The Ophthalmic Publishing Company. 1923. (Imp. roy. 8vo, pp. viii+393.)

*How to Become a Nurse*, edited by the late Sir HENRY BURDETT from 1899 to 1915, and now, in its tenth edition,<sup>11</sup> revised by E. MARGARET FOX, R.R.C., still justifies its useful purpose by supplying exact information to would-be nurses. The book consists of a detailed list of general, infectious, and mental hospitals in the United Kingdom, Australasia, Canada, and South Africa, with an index.

The twelfth edition of DELAFIELD and PRUDEN'S *Textbook of Pathology*,<sup>12</sup> revised by Dr. FRANCIS CARTER WOOD, retains its general characters as regards the arrangement of subject-matter, the additions and alterations being confined to textual details and new illustrations. The volume is divided into three sections, the first dealing with general pathology, including etiology, circulatory changes, degenerations, inflammation, animal and vegetable parasites, infectious diseases and the specific fevers, malformations, tumours, poisons, general and metabolic diseases, and the lesions in certain forms of death from violence; the second part comprises the special pathology of the several organic systems; and the third part deals with *post-mortem* examinations and microscopic technique. The subject-matter, therefore, extends over a wide field, and although the volume is large the descriptions are necessarily concise, as is the case in all books of this nature. In view of this fact and of the importance of students supplementing their textbook knowledge by referring to special treatises the author has greatly amplified the references to the literature, so that these form a considerable portion of the text, and constitute a distinct feature of the book. The references are conveniently placed at the foot of the pages containing the subject-matter to which they refer. The book forms a sound basis for the study of general pathology.

<sup>11</sup> *How to Become a Nurse—The Nursing Profession—How and Where to Train*. Tenth edition; revised by E. Margaret Fox, R.R.C. London: The Scientific Press, Ltd. 1923. (Cr. 8vo, pp. 353. 4s. net.)

<sup>12</sup> *A Textbook of Pathology, with a Final Section on Post-mortem Examinations and the Methods of Preserving and Examining Diseased Tissues*. By Francis Delafield, M.D., LL.D., and T. Mitchell Prudden, M.D., LL.D. Twelfth edition. Revised by Francis Carter Wood, M.D. New York: William Wood and Co. 1922. (Roy. 8vo, pp. 1354; 17 plates, 809 figures. 63s. net.)

## PREPARATIONS AND APPLIANCES.

## Novoiodin.

NOVOIODIN is an iodine compound of hexamine, with the formula  $(CH_2)_6N_4I_2$ ; it contains 60 per cent. of iodine, and on decomposition in presence of water it can liberate formaldehyde. It is an amorphous light brown powder, which is insoluble in the usual solvents, but can easily be made into a suspension with oils or glycerin. Novoiodin was investigated in 1911 by Eugling (*Zentralbl. f. Bakt.*, Bd. 60, s. 397, 1911), who found that it had about ten times the disinfectant activity of iodoform, and that the disinfectant action of the drug depended on the liberation of iodine when brought in contact with tissue fluids or pus. Numerous clinical reports have since appeared describing the action of novoiodin as a disinfectant for wounds, teeth, skin, etc. Novoiodin was used extensively by the Austro-Hungarian Red Cross in the recent war. The reports show that novoiodin is a more efficient disinfectant than iodoform, and it also has the advantage of being cheaper and also odourless. It can be obtained in this country through Messrs. Ronsheim and Moore, 11a, Wormwood Street, London, E.C.2.

## Tonsil-bed Compressor.

Mr. G. Gushue-Taylor, M.B., B.S., F.R.C.S. Eng. (Barkingside, Essex), writes: In the *JOURNAL* of July 1st, 1922 (p. 18), appeared a short description of a haemostatic twin tonsil-bed compressor which I had devised for use after removal of tonsils. Extended use of the instrument at the aural department of the London Hospital,

and in my hands at Dr. Barnardo's Homes, has proved it to be very efficient. It had a defect in the curve of its blades which has now been remedied, and the form of the blade in the improved instrument allows the swab to be placed in the long axis of the tonsil-bed and to come into apposition with the whole bare area. It is, as altered, more easy to place the swab in the tonsil-bed, and it remains in position more securely and quite comfortably. In one case in which it was applied to the child was able to go to sleep with the compressor applied to the bleeding area. The instrument is made by Messrs. May and Phelps, London.

research, stimulated professional enthusiasm by lectures and prizes, and might with advantage investigate patent medicines and influence some control over them. The journal had passed under the names of the *Provincial Medical and Surgical Journal* (1830), the *Association Medical Journal* (1853), and the *British Medical Journal* (1857). He must not repeat what Sir John Bland-Sutton had said, but it was impossible to suppress the admiration he felt for the present Editor, and for the great work he had done, was doing, and, he hoped, would long continue to do in making and maintaining the high standard of medical journalism in this country. (Applause.)

"The Chairman."

Dr. Wallace Huxley proposed the health of the Chairman and praised the wisdom and tact with which for over three years he had conducted the business of the Council. He had sacrificed time and money and health in the interests of the Association, but they all rejoiced to see his health very much restored. (Applause.) He referred especially to his work in bringing about a linkage between the Association and the Society of Medical Officers of Health, and in securing the new building in Bloomsbury which was to be the home of the Association. They all hoped that during his period of office they would see the buildings completed.

The toast was drunk with much heartiness, and Dr. Bland, in reply, thanked them for the kind thing they had done, even though it was wholly out of order. It had been a great pleasure to him to take part in the work of the Association.

## FELLOWSHIP ADDRESS OF THE AMERICAN COLLEGE OF SURGEONS.

At the convocation ceremony of the American College of Surgeons in Chicago, on October 26th, the Honorary Fellowship of the College was conferred upon Sir William Ross, President of the Royal College of Surgeons in Ireland, and upon Mr. A. E. Webb-Johnson, C.B.E., D.S.O., F.R.C.S., Honorary Surgeon to the Middlesex Hospital and Dean of its medical school. Mr. Webb-Johnson is visiting the United States in response to an invitation to deliver an address at the meeting of the College. The Fellowship address was delivered by Sir William Wheeler.

### SIR WILLIAM WHEELER'S ADDRESS.

Sir William Wheeler began his address by expressing his thanks and sincere appreciation of the honour that had been done him in electing him an Honorary Fellow of the American College of Surgeons, and of the high compliment that had been paid him by the Regents of the College in inviting him to address them on the tenth anniversary of its foundation. He wished to acknowledge, he said, with no feigned gratitude, the spirit of brotherhood which surrounded him on all sides.

The distinguished past-president of the College, Dr. John B. Deaver, who had recently vacated its chair, had justly pointed out that the American College of Surgeons, though on national in name, was international in scope, and was carrying on the principles of the profession for the good of humanity. The American College had demonstrated to the world that medicine and surgery, and, indeed, scholarship generally, were independent of nationality and knew no distinction of race or speech. To Irishmen especially, throughout their entire history, America had exercised an attraction as if by some magnetic influence, and its surgical work and literature were as well known in Ireland as they were in America itself. It was the proud privilege of the Irish College of Surgeons, over which he had the honour to preside, to number among its honorary Fellows no fewer than nine of the great American surgeons of the day. The Irish College had been chary in the bestowal of that honour during the one hundred and forty years of its existence, and the simultaneous bestowal of the honorary Fellowship on nine surgeons from the same country had no precedent in the previous history of the College. When, however, it was proposed to enrol the name of the President of the American College, Dr. Cushing, together with the names of Drs. William and Charles Mayo, Dr. Ochsner, Dr. Keen, Dr. Hart, Dr. Finney, Dr. Brewer, and Dr. Crile, not a single dissentient voice was heard, and it was felt that an occasion had arisen when time-honoured precedents ought, for the moment, to be disregarded. It was but natural that

they in the surgical profession in Ireland should feel an admiration for the surgeons of America. Many of the greatest of them bore Irish names, and blood was thicker than water. He expressed the hope that the members of the medical profession of the two hands might be joined in brotherhood for ever in the service of mankind.

Naturally, his thoughts at the moment turned much on travel and its influence on the progress of surgery, and in that connection he was reminded of the words of a great Canadian, Osher: "Let me suggest that the lines of intellectual progress are veering strongly to the West, and I predict that in the twentieth century the young English physicians will find their keenest inspiration in the land of the setting sun." Osher had, as they in Ireland had—to quote the words of his father-in-law, Lord Shaw—"A love for the land where dreams come true; dreams of more secure reward for honest industry; freedom from the irksome restraints and conventions which have qualified their day; of equality, frankly avowed and sincerely prized." Osher deplored contentment with second-hand knowledge derived from books; he urged scientists to add their own contributions to the general store of knowledge and to gain familiarity with workers abroad. Those who lived in a small island found it difficult to realize and to attach sufficient importance to these matters. It was very difficult, even for an Irishman, to live on an island and not to have an insular outlook; but difficulty was a severe instructor, and they were learning from their difficulties as well as from their mistakes. "Just as soon as you have your second teeth," said the great medical philosopher, "think of a change; get away from the nurses; cut the apron strings of your old teachers; seek new ties in a fresh environment." Osher, Canadian born, with a great wide outlook, deplored intellectual insularism and that disease known as provincialism, in which "as if by the touch of the wand of some malicious fairy, the victim slips adolescence, maturity, and manhood, and passes to senility, wrinkled and stunted, a little old man amongst his toys." With the limited vision which was given to those who lived and worked in a small country two other defects were wont to develop as the result of want of travel—namely, swelled head and writers' cramp.

Much of the early history of medicine in Ireland was traditional and legendary, but the people of bygone days were not devoid of literary culture. It was known, on the testimony of Plinius, that women studied medicine in ancient times, and the same appeared to be true of Ireland as of Rome and Greece, for in the *Book of Galen* of the name of reference was made to a female physician of the name of Euba. It was further interesting to note that the Royal College of Surgeons in Ireland was the first modern licensing corporation in Great Britain and Ireland to admit women and to appoint them to the highest offices in its gift. There was no lack of references to Irish medicine in past ages. The *Book of Leinster* recorded the tragic fate of Conchobhar Mac Nessa, King of Ulster, who died in A.D. 57, and related that he was wounded in the head by a missile from the sling of an enemy, and attended by a physician of the name of Eingen. The wound was closed, the sutures used being of gold, as corresponding in colour with the King's hair. Concerning the clinical instinct of Eingen, it was stated that "He could know by the time which rose from a house the number that were ill in the houses and every disease that prevailed in the house." The ancient laws of Ireland, the Brehon laws, which were codified at the request of St. Patrick in A.D. 438, referred to the remuneration and responsibility of medical men. If a person wounded another, the aggressor was obliged not only to pay a fine to the injured man, but also to provide him with maintenance and skilled medical care—a profession of physics passed from father to son in those days, regulating the lapse of which could not but be regretted. The ancient Irish doctor was shrewd enough to travel, and a representative Irishman, not only of the medical but of other professions also, remained abroad, and were to be found occupying distinguished positions in the various schools of Europe. Ancient manuscripts proved how admirably Irish physicians kept in touch with the advance of learning in Continental centres. A thirst for knowledge, and a keen observation of the sick under their care, raised medical and surgical science to a high pitch of perfection in the sixteenth century progress came to a standstill. Ireland was torn by strife, and no shelter for learning remained. This decline was intensified by the failure of the Irish to grasp the significance of the revolution in the art of printing which followed the introduction of the printing press years after its adoption by the progressive of other lands. The early printed records of the great European physicians were not imported, and no Irish medical literature existed in print at that time. This period of depression, however, passed,

nevertheless accommodate conveniently those of normal physique. Of such cars we have constructions of British origin and quality second to none, and to-day they are offered at quite amazingly low prices.

#### A YEAR OF IMPROVED CARS AT LOWER PRICES.

At the very bottom of the list we have the 2-cylinder air-cooled Rover now made available either with two seats and dickey or with "chummy" body, at £139 each only; this is the cheapest all-British car in the exhibition. We have also the 2-cylinder air-cooled Stoneleigh which, as a 2/3-seater, is available at £155; and in the water-cooled 2-cylinder type we have the 7-h.p. Wolseley available with ample leg room, at £199. Passing to the 4-cylinder category we find the 11.9-h.p. Morris-Cowley listed at £225 as a 4-seater; and a machine that is a classic of its kind, the overhead valve 4-cylinder 10-h.p. engined Wolseley, built by Vickers's motor manufacturing works, is available complete as a 2-seater with dickey at £250 only. There is shown for the first time at this exhibition the new 11.9-h.p. overhead valve 4-cylinder engined Standard that was introduced during the summer, and has been developed. The distinctive point of this machine is that, though it is a light car and is economical as to fuel, taxation, tyre wear, and so forth, nevertheless it is not a small car as regards the accommodation available for the occupants. On the contrary, it is on full-size car scale. Therefore, we have here what is truly the first light car, because in this case lightness is not achieved by any curtailment of accommodation. This machine is available with either 2- or 4-seat all-weather body at £235 only in each case.

#### HOW COST HAS FALLEN.

What has been occurring in the matter of prices cannot be better illustrated than by citing what has happened during the last three years. For instance, the 10-h.p. Wolseley was listed two years ago at £475; last year at £385, and it has come down this year to £250. Admittedly, in this case there is a difference in the specification as to the material of the upholstery and certain details like that. But the car remains a complete all-weather 2-seater of exactly the same accommodation; and the chassis is improved in detail. In regard to the 2-cylinder Wolseley, the price two years ago was £295; last year it was £255, and this year it is £199. This machine is a better one to-day than it was two years ago. The 8-h.p. Rover was originally introduced after the war—it has been on the market four years—at £300 when prices were at dizzy heights. Two years ago it had been brought down to £220; last year it was listed at £180, and to-day it is available at £139, and, again, we have to consider that this year it is an improved product. The air-cooled Stoneleigh, produced from the designs of Armstrong-Siddeley's engineers, and built under the direction of that firm, was £225 last year and £185 this year; it is available in an improved form for £155 to-day. The prototype of to-day's 11.9-h.p. Standard model had a smaller engine, a smaller chassis, and was altogether a different proposition, not in any way comparable in merit with the new type; yet two years ago that prototype was deemed extraordinarily cheap when it was introduced at £315, and last year, when certain processes of development had been in operation, it was also held uncommonly cheap at £295; but to-day, in a fully developed form with a much larger engine, larger track, longer wheelbase, and ampler accommodation, it is £235

#### ENTERPRISE IN THE MIDDLE RANGE.

What has been happening in regard to the prices of middle-sized British cars? The same thing. Take the case of the famous 12-h.p. Rover car of 13.9-h.p. Treasury rating. The first cars available after the war cost £725; two years ago the figure was £650; last year it was £550; and to-day the 4/5-seater is £495 in altogether improved form, as instance the standardization of shock-absorbers and the provision of four instead of three speeds forward, together with many other improvements in minor details. This Rover model—proved by medical men years before the war—is now to be listed at its Treasury rating and is styled, therefore, a 14-h.p. (instead of a 12-h.p.) type. Again, take the 14-h.p. overhead valve engined Sunbeam car that was introduced two years ago at £725 and listed

last year at £685. The price remains the same to-day as last year; but there is a notable difference in the product. The most obvious of the many improvements included in this type is the provision of special front wheel brake system which this firm, that attained the foremost position in competition last summer by winning the blue ribbon event of the motor racing world, the Grand Prix of the Automobile Club de France, has evolved during many years of first-class, international, long distance road racing. Indeed, it was the first British firm to introduce brakes to all four wheels as standard on its largest 6-cylinder model last year, for the front wheel brakes on the 7-h.p. Austin are of a construction that is not concerned with the particular problems involved in this development. If I could go through the list item by item, it would be found that most cars represent better value for money to-day in that there is more in each machine as listed now than formerly; instance the extraordinary Overland de luxe model, the equipment of which is a catalogue in itself; and which sells for £295. Of course cases could be cited in which prices have been cut in even greater proportions, but I have sought deliberately examples of motor wares for which there is demand, each of which has attained an honourable reputation in its line, and is marketed by firms not forced to jettison their stuff but which are, on the contrary, trying to work at a reasonable commercial profit. That is essential if the motor buyer is to be given service; without which, no matter what price he pays for a car, it is a dear bargain because he cannot get, among other things, spare parts at commercial prices as and when he wants them. Unquestionably a very large proportion of members of the trade and industry is in the position of having goods to jettison, hence prices are being cut right and left. That, however, the individual must judge for himself when he inspects the display. After all, there is a vast difference in the appearance of those machines which are plainly a drug on the market, and those of some pedigree for which there is equally plainly a current demand.

#### HAVE PRICES AND COSTS TOUCHED BOTTOM?

One of the points concerning which the medical man will certainly be curious is this: How am I to know that if I buy a car now I am getting it at about bottom price, at least for this year? A matter which one would not bring before the public in general may be mentioned here in a semi-confidential way to members of the profession that they may judge for themselves. Dealing with cars for which there is a demand, and without indicating definitely whether the given machine is of British or of foreign origin—I shall cite points which happen to concern both categories—of machines that are being actually built now, as distinct from those which were built some time ago and which have to be got rid of somehow, one manufacturer is being supplied with sparking plugs at 4d. each though they cost shillings to make; and another manufacturer, also of big output, is being supplied with carburettors at half the bare cost of producing the castings. I could cite examples, too, in regard to electrical equipment and other accessories. In fact, one of the notes of the year is that machines are being supplied with quite an extraordinary amount of auxiliary gear: I will instance the elaboration of the instrument board, the provision of clocks, gauges, reflectors, tyres, and so forth. Here we have the key to the riddle. The accessory industry in general is in a parlous state and much stock has to be jettisoned by some firms. The car manufacturer avails himself of that opportunity both to make his vehicle more complete and to pass the benefit, without any profit to himself, direct to the buyer, because he realizes that it is to the advantage of both parties. Therefore much of the reduction in car prices is due to the fact that the accessory industry in general is supplying the manufacturer at losses that certainly represent an average of 10 per cent. It is a mysterious method by which the bankers seem to be content to keep accessory factories going; if they were not liquidating stock in this way, in many cases they would be closed in three weeks. Those that understand the case can judge for themselves whether accessories to be made henceforth can be produced and supplied under such conditions. I am convinced they cannot. We have touched rock bottom.

symptoms and even his change in appearance and yet completely fail to draw the obvious, or almost obvious, conclusion in a diagnosis of his malady. How far his blindness to the nature of his own ailment went was shown by Dr. Mark's reading without illumination a pamphlet on acromegaly which had been sent to him by a friend; yet his brother-in-law, finding the pamphlet on his table and reading it recognized in a few minutes that it was a description of the malady from which Mark was suffering. He thought he had gone to a curious feeling of malaise he had; he had his eyes examined and wore glasses for astigmatism, he had turbidness of his nose trouble, he wore a denture for undue separation of his teeth, he had to discard hats and gloves and boots because they grew too small for him; and yet he was blind to his own signs, and he had not the gift to see himself as others saw him. In his own striking words: "For some fifteen or twenty years, each day when I looked into the glass to brush my hair or shave, there was a typical acromegalic literally staring me in the face; yet I never recognized the fact." "The old proverb, 'Physician, heal thyself,' may in the future and another to keep it company—Physician, diagnose thyself."

## England and Wales.

**St. Thomas's Hospital Medical School.**  
The annual old students' dinner of St. Thomas's Hospital was held on October 26th at the "Pines" Restaurant, with Mr. H. H. Bartley, F.R.C.S., consulting surgeon to the hospital, in the chair. The large company present, numbering 215, included Sir Charles Sherrington, President of the Royal Society; Lieut.-General Sir William Teshman, Admiral J. Chamberlain, Medical Director-General of the Admiralty; Sir William Horwood, Commissioner of the Metropolitan Police; Sir Havelock Charles, and Sir Squire Spriggs, together with Sir George Makins, Sir Seymour Sharkey, Sir Hector Mackenzie, and many other members of the consulting and active staffs of the hospital. The toast list was as short as the speakers were concise, and the chair in proposing prosperity to St. Thomas's Hospital and Medical School, remarked that long speeches were out of place at a function which was meant to be a social gathering and not an occasion for instruction. He complied with the toast the names of the Hon. Sir Arthur Stanley, Treasurer of the Hospital, and Sir Cubbert Wallace, Dean of the Medical School. Sir Arthur Stanley began by assuring his audience that "the hospital is all right," though he hastened to add that it always had been short of money and always would be. Among recent developments, plans had now been got out for adequate club rooms in the college houses to be built on the other side of Lambeth Palace Road; for this purpose £7,500 were already in hand. Sir Cubbert Wallace first responded for the school and then offered a welcome to the guests. He covered a great deal of ground in a short space of time, and in so doing rather turned the edge of his own suggestion that speeches of this kind would be better if they were printed and circulated beforehand and "taken as read." Among the outstanding features of the year was, he said, the new medical curriculum; in this matter the colleges in London had gone further than any other body. In regard to the relations between the University of London and the medical schools of the metropolis, he wondered whether this increasing centralization was altogether an advantage. He recorded with gratitude the gift of £5,000 from the Dunn bequest to establish biochemical laboratories; and another £5,000 to endow them; for the allocation of these sums a special debt was due to the good offices of Sir Walter Fletcher. The number of students was still very large and the recent falling off in entries had been welcomed by those in authority at all the medical schools. Among the honours and distinctions conferred on Sir Hector Mackenzie, and the election of Mr. Basil Hall to the presidency of the British Medical Association for its Annual Meeting at Bradford in 1931. Lastly, in proposing the chairman's health, Sir Cubbert Wallace said that no eulogy of Mr. Bartley was needed in

**INCOME AND EXPENDITURE OF LONDON HOSPITALS.**  
The King Edward's Hospital Fund for London has published its statistical report on the income and expenditure of 113 London hospitals for the year 1932. The hospitals are grouped as follows: 12 general hospitals with medical schools; 10 general hospitals without medical schools, and with an average of over 100 beds in daily occupation; 11 smaller general hospitals; 3 consumption hospitals; 5 ophthalmic hospitals for women; 8 hospitals for children; 5 ophthalmic hospitals; 5 hospitals for epilepsy and paralytics; 8 lying-in hospitals; 14 cottage hospitals; and 34 other hospitals. It is shown that the income of these 113 hospitals (apart from special distributions such as the emergency grants from the King's Fund and the National Relief Fund, and by the Voluntary Hospitals Commission) increased from £1,470,000 in 1931 to £2,401,000 in 1932, and £2,566,000 in 1933; in 1932 it was £2,398,000, a slight decrease. The special distributions which are omitted from these figures included, in 1932, £245,000 from voluntary sources—namely, from the first and second instalments of the proceeds of the Combined Appeal, and it was part of the scheme of this appeal that for an agreed period the co-operating hospitals should suspend all independent appeals. An analysis of the various sources of incomes shows that of the total amount £505,000 came as income from investments, £524,000 as voluntary gifts (subscriptions, donations, etc.), and £769,000 as earnings (from patients, public authorities, and other sources). To the total ordinary income is to be added the extraordinary income, comprising £172,000 from legacies, and £28,000 from other sources, including grants from the King's Fund and in reduction of general fund debt. The difficulties of the hospitals, as compared with the conditions before the war, were produced by increase of expenditure and not by decrease of income. It is satisfactory, therefore, that expenditure now shows a substantial decrease. After having risen from £1,192,000 in 1913 to £2,782,000 in 1930, there was, therefore, a net aggregate deficit for the year 1932, amounting to £241,000. A further analysis shows that 88 of the hospitals had surpluses for the year amounting to £67,000, and 55 had deficits amounting to £241,000.

**A SCIENTIFIC TEACHER CLASS IN LONDON.**  
We are informed by the Education Officer of the London County Council that at the suggestion of Sir Henry Gavan, the London County Council's consulting specialist for tuberculous children, an experiment was conducted at Storey House open-air school, Clapham Common, during the summer months, to ascertain how far sunlight treatment could be utilized in day open-air schools. Thirty-five boys were selected, with their parents' consent, by the school medical officer. The head master reports that during the first week the lads worked, at their class and manual lessons, as usual, but that they were nothing more than their brethren, in light shirts, short pants, socks and shoes. The second week, as a result of a few weeks' treatment, the boys appeared more alert, more energetic, and particularly happy under the new conditions. On their return to school after the summer holidays, it was necessary to acclimatize them again, but this time for only one or two days were they compelled to wear shirts whilst at work. The school medical officer reports that the results of the treatment were sufficiently promising to make it highly desirable for the experiment to be continued next summer, and the Education Committee on October 24th decided to do so.

**Barriers Dentists' Hospital.**  
The eleventh annual meeting of the British Dentists' Hospital was held at the Camden Road headquarters on October 27th, with Sir Henry Baldwin, C.V.O., the new President, in proposing the chairman's health, Sir Cubbert Wallace said that no eulogy of Mr. Bartley was needed in

## A WORD OF WARNING ABOUT FRONT WHEEL BRAKES.

Therefore the only thing I can do in the interests of medical men is to advise them to inquire carefully into the history of the fitting of front wheel brakes to any given car. Of the French industry in general it may be recorded to its great honour that it has had five years' experience of front wheel brakes. The majority of the French builders of cars of any quality are standardizing systems which embody, in any case, servo mechanism, chiefly under the Perrot-Hallot patents. M. Henri Perrot was the first to discover some of the other basic principles involved in the safe application of brakes to the front wheels. He is really the father of the whole movement. Italy sends a notable version of front wheel braking in the 6-cylinder 30/40-h.p. Fiat, which is a chassis possessing remarkable qualities for the needs of any who may have occasion for a covered carriage to serve often as an economizer of time over the railway service, and which shall be of strictly reasonable prime cost and a high degree of refinement and efficiency. This system should be studied. A bare chassis is shown with the now well proved hydraulic control which this firm has been one of the first to bring to a practical stage, as a result, incidentally, of its unsurpassed experience in first-class racing events.

A note of the year is that Sunbeam was the only firm to standardize last year a front wheel braking system of genuine engineering merit, wherein the problems involved were faced frankly and solved; this year the British industry is emboldened to bring forward great numbers of variants. Moreover, after several years of experimenting the American industry has devised some standardized front wheel braking systems and has, too, provided more types, such as the Marman, than are marketed in this country. But in general it is important to note that M. Henri Perrot, whose patents are worked under licence in America by such firms as General Motors (who market the Buick, the Oakland and Cadillac 4, 6, and 8-cylinder cars that are now fitted with front wheel brakes), has expressed the opinion in writing in the U.S.A. technical press that the American industry in general is in the same state in regard to four-wheel brakes to-day as was the French industry five years ago. As to our own types, several car builders, including Bentley, Daimler, the 21-h.p. Lancaester, Maudslay, Rover, Sunbeam (14/40-h.p., 16/50-h.p., 20/60-h.p., and 24-h.p. types), and Vauxhall have well thought out schemes standardized on certain models. In the cases of the 30-h.p. 6-cylinder Armstrong-Siddeley and the 14-h.p. Bean, and in regard to the 20/70-h.p. Crossley type, such accessories are supplied as extras at the buyer's option. But in regard to the more powerful 6-cylinder cars made in Britain, it is observable that neither Lancaester with the 21-h.p., Napier with the 40/50-h.p., nor Rolls-Royce with the 40/50-h.p. 6-cylinder chassis furnish brakes to the front wheels. The two former, however, have considerably increased the diameter and area of their brakes on the back wheels. Napier is the only firm concentrating on one large 6-cylinder model only, which is available in a longer wheel-base type, and Rolls-Royce introduces a longer wheelbase on the big 6-cylinder chassis.

## NEW TYPES AND NEW CAR BUILDERS.

As Rolls-Royce introduced a 20-h.p. 6-cylinder overhead valve engine car last year, so Lancaester, hitherto concentrating on a large 6-cylinder, introduces this year a 21-h.p., overhead valve, 6-cylinder, monobloc engine chassis with front wheel brakes, four speeds forward, and the Lancaester suspension and worm drive features. Rover introduces a nominal 21-h.p., 6-cylinder, side valve engine, four-speed, worm-driven car with Perrot-type front wheel brakes; Maudslay enters the car industry with a 15/80-h.p., 6-cylinder, overhead valve engine, four-speed chassis of notable design; and Sunbeam introduces a 16/50-h.p. and a 20/60-h.p. overhead valve engine chassis, both with 6-cylinder engines and brakes to all four wheels on the special Sunbeam principle. The 4-cylinder 14-h.p. Armstrong-Siddeley, 4-cylinder 14-h.p. Bean, 11.9-h.p. Standard, and 12/30-h.p. Sunbeam types make their debut at the show. Of course, there are introduced some new makes of cars, those that will be seen for the first time at the enlarged

Olympia, including the 10-h.p. Triumph that was brought out last summer, the 10.4-h.p. Windsor, the 12-h.p. Westcar, and the 24/80-h.p. "straight-eight" Beverley-Barnes. The last named is a £28 tax, overhead valve, 3,994 c.cm. engine volume machine with a gearbox giving three speeds forward, spiral bevel-driven back axle, brakes on all four wheels at a chassis price of £750. The builders are Lenaerts and Dolphens of Beverley Works, Willow Avenue, Barnes. But despite the chassis price being moderate, this is too ambitious a vehicle for the average medical man. Therefore, in connexion with the problem of designing front wheel brakes in general I may state that it was impossible at this stage to get a better example of what has been learnt in the five years during which these accessories have been employed in France, where over 20,000 individual private owners have had experience of them, than in the 12-h.p., 4-cylinder, overhead valve engine, four-speed Delago car which is on exhibition at the show. Hispano-Suiza, Peugeot, and Renault have also done notable pioneer work in this connexion. That will give an idea of the basic principles that have to be dealt with. It illustrates admirably the Perrot-Hallot servo mechanism and other patented schemes. Among the Americans who work under some of these patents, it is observable that in the Buick car introduced by General Motors the four-wheel braking system works on the principle of shoes expanding in drums on the rear wheels and contracting bands on the front wheels; while in the Cadillac the process is exactly reversed. Continental and British makers do not favour the use of contracting bands for the reason, among others, that it is not possible to get absolutely even pressure over every fraction of the contact surfaces. General Motors is the largest individual corporation in the world producing cars, and in the case of three of its makes (including the Oakland) it has fitted front wheel brakes this year, after several years of experiment. Against this, on the Chevrolet and Oldsmobile cars, which it also builds, front wheel brakes are not furnished this year.

## NEW LIGHT WEIGHT, SILENT, COVERED BODIES.

Quite the most notable development in regard to coachwork for the medical man is the Weymann cheap, light weight, silent, durable, patented covered body, which was dealt with at some length when the recent Paris Automobile Salon was reviewed. It was shown by Delago and Talbot-Darracq. The system is illustrated at the Olympia exhibition by those builders, and among other licensees, Daimler, Rover, and Sunbeam, who are standardizing this class of body, which can be made as commodious as the chassis can accommodate, yet the total weight will be not more than that of an open body. The principle embodies aircraft engineering practice as regards the construction of the framing, the jointing, the general use of wood, and so forth. Traditional coachwork practice is reversed completely in that the doors, sides, back, and roof constitute one member entirely independent of the floor and seats, which are a separate unit erected on the chassis. The hinges, the cam action handles, the methods of attachment, the grooves wherein the windows slide up and down, and so forth, are each the subject of a patent, the result being lightness, durability, low cost, and absolute silence. The last is a great factor for saving fatigue in the case of those who have to drive more or less all day long, and often at night. It is possible to speak in this type of covered body without raising the voice any more than one does in a room. I have found that to be a true claim. There is no squeak or rattle. This is a type of body, too, which does not lose its original gloss but, on the contrary, looks as well after long use as at the beginning. Against that, it never has the mirror-like, showroom finish of the average car of to-day, which loses its pristine brightness within, unfortunately, less than three months, never to recover it again. Talbot put one of these closed bodies on a 12-h.p. chassis, and it actually weighed 80 lb. less than the open touring type of car. The fabric used for the panelling is synthetic leather, which can be dusted as well as washed by unskilled labour without injury—an important matter, for if one attempts to dust an ordinary car the varnish surface is cut. From that moment the process of deterioration is exceedingly rapid.

and they reaped a rich reward in the greater influence and position of the profession itself. The surgeon had been considered of late the most successful member of the profession; but he was now being pressed hard by the scientific physician, the metallist and clinical pathologist, and the radiologist, and this was very disadvantageous. Dreyer's researches were opening up new hope in the cure of some septic affections. Insulin had rendered the treatment of diabetes mellitus exact and successful. Radiology had not been content in making visible the uterus, but had invaded the inner recesses of the brain, and by means of ventriculography had shown the closed foramen of Magendie or the blocked aqueduct of Sylvius. To replace the fluid of a hydrocephalus by air, then by the x rays to demonstrate the obstruction to the circulation of the secretion of the choroid, and finally to remove this obstruction by probe or otherwise, was surely an aim worthy of the keenest intellects and most delicate manipulation of the age. Radiology spread into pure therapeutics and gave promise of relief, perhaps of cure, in one of the most horrible of fatal diseases, cancer of the rectum. Their treatment of wound shock was another example of advance, and the results by the present method by the removal of all bruised and injured tissue gave results far beyond the hopes of pre-war days. All these advances were the results of the communism of science and the internationalization of medicine; and all should learn to study in this broad spirit, and recognize the provincial hospital as a constituent part of a world-wide institution. Mr. Rullerton urged the spirit of research, and pointed out that all could contribute; Edward Jenner in former years and James Mackenzie in recent times did their best work as general practitioners. Note-taking was much more than a preparation for an examination; it was an education in full and accurate observation and in the proper record of the results, and was indispensable both in practice and research. The hospital of the future would be known by its records, from beginning to end of the disease, reliable, serviceable; and such notes all students should be trained to take. The lecturer concluded by referring in happy vein to the long term during which Professor Sinclair was connected with the profession, and to his many years of skilled and arduous work for the hospital. He welcomed Mr. McIntosh to the staff as a worthy colleague and as a gain to his teaching power, and he congratulated Professor Thomson on his recovery from his tedious and trying illness. Dr. Calvert proposed and Mr. Craig seconded a hearty vote of thanks to the lecturer for his valuable and eloquent address, and this was conveyed to him by the chairman and acknowledged.

On the evening of October 22nd, Professor J. Sinclair, C.B., F.R.C.S., was entertained to dinner by his colleagues on the staff of the Royal Victoria Hospital, Belfast, on the occasion of his appointment to the consultant staff, and was presented with an oil painting, "Littlehampton Harbour," by B. W. Leader, the chairman, Mr. Mitchell, proposed in happy terms the guest's health, and said that, although they would all miss him from the more active and laborious work of the visiting staff, they hoped the separation was otherwise only verbal. Mr. Sinclair replied. A largely attended public meeting was held at Coleraine to consider the alleged action of the urban district council with regard to the serious outbreak of typhoid which has occurred and its supposed causation by impure water. It is stated that some sixteen cases of typhoid fever and a large number of cases of diarrhoea have occurred in the town since the beginning of September. At a meeting of the urban council one of its members said that one could not walk six yards without seeing that the water supply was being contaminated with manure. The following resolution was unanimously passed by the meeting: "That the water supply for the town of Coleraine having been pronounced by Professor Wilson and Dr. Patrick as unsafe to drink, and a resolution having been unanimously passed at a public meeting of the townspeople held in the Town Hall on Tuesday, September 25th last, calling on the Urban

Sir, I have read with the greatest interest Mr. Souttar's review of the reasons which have led the London Hospital to abandon the surgical unit experiment, and venture, since the matter is of the utmost importance to our great teaching schools, to add to it some notes on our experience at the Middlesex Hospital. Having watched the innovations in the methods of clinical teaching with the greatest interest and anxiety, we, at the Middlesex Hospital, declined, after the fullest consideration, to adopt the professorial unit system, fearing that, in spite of its apparent advantages, it might fall far short of the very reasons which Mr. Souttar has given. We held, moreover, that the old system could be so varied as to attain all the advantages of the unit system without the drawbacks which have now led the London Hospital to abandon the original whole-time professoriate, and that this development could be effected at a less cost. We sent a reasoned memorandum to the University Grants Committee, and gave them a definite scheme for which we asked their assistance, and, although this assistance was not forthcoming, we were so confident of the merits of our scheme that we determined to give it a full trial. Briefly, then, we attached to each surgical, medical, and obstetrical firm a whole-time registrar, whose duties consisted in assisting in clinical teaching, carrying out and coordinating pathological investigation, following up cases, and in collaboration with his chief, undertaking definite clinical or pathological research. The opportunity of filling these posts, which carry a salary of £500 a year, and are tenable for three years, appeals to men who have completed their higher qualifications, are glad to gain further clinical and pathological experience, together with the opportunity of doing some teaching. While it is probable that the details can be still further improved, it is quite certain that this plan has increased enormously the value of clinical teaching in the hospital, and of the services rendered to its patients, without in any way restricting the field of practice of the honorary members of the staff. For my part, I can unhesitatingly say that in my own firm I am daily conscious of the increased efficiency that results from the close co-operation of my registrar. The clinical records of my cases are both of more immediate and more permanent value as a result of his supervision. With his help I have been able to carry out more statistical work, and to follow up cases further than I could otherwise have done—one most important aspect of the research work which it is his duty to carry out. Furthermore, the interest of the students in the cases is fostered by the certainty that they will not miss seeing for themselves the pathological material provided by operation or post mortem, demonstrated by a registrar familiar with all other features of the case—an essential preliminary to the final instruction which they receive from the members of the honorary staff. In addition, his presence in the theatre for the collection, and, if necessary, immediate examination of pathological and bacteriological material ensures the full value of such examinations according to the patient, to myself, and to the students. He acts as a link between the clinical and on the surgical and on the pathological departments. My colleagues, both on the surgical and on the medical side, are equally impressed with the advance which the creation of the appointments has made, and we are confident that as we perfect the scheme we shall build up

## Correspondence.

### THE UNIT SYSTEM IN SURGERY.

District Council to appoint the best procurable waterworks engineer to examine and report on the whole scheme, and to have his report carried into effect without delay, and this resolution having been sent to the Council for their immediate attention, and having been considered at the meeting of the Council on the 1st inst., but no action taken in making such an appointment, we, the inhabitants of Coleraine in public meeting assembled on this 10th day of October, 1923, hereby request the Ministry for Home Affairs to hold a public inquiry into the whole matter at the earliest possible moment.

Royal Automobile Club to organize comprehensive trials low pressure tyres in 1924.

In the carburettor section interesting exhibits are the Johnson power jet type; and the newest triple diffuser. There is also a special Zenith type for Morris cars. Other exhibits on the Zenith stand include air strainers and controls for standard types of carburettors; also a range of special inlet pipe fittings enabling this system of carburation to be applied to any make of car.

A development in connexion with sparking plugs is a miniature Lodge type for use on miniature engines; also a fitting in positions where it is impossible, or difficult, to employ an ordinary size plug. This model is known as B. Another Lodge exhibit is the well known priming plug which facilitates starting an engine in cold weather. This ingenious device has been improved in several details.

The Gamage display in the accessory section is a minor exhibition in itself. Incidentally, it is interesting for the wide range of foot-warmers; and the various types of gloves and gauntlets for keeping the hands and wrists warm.

### THE NOBEL PRIZES IN MEDICINE.

The Nobel prize in medicine for 1923 has been awarded jointly to Professor Macleod, F.R.S., and Dr. Banting of Toronto; that for 1922 jointly to Professor A. V. Hill, F.R.S., University College, London, and to Professor Otto Meyerhof, of the University of Kiel.

The award to Professor Macleod and Dr. Banting is in recognition of their researches into the action of insulin and its use in the treatment of diabetes. As we have so recently given a full account of these researches, have published Professor Macleod's address to the International Congress of Physiology in Edinburgh, and as we are about to publish the Cameron Lectures on the nature of control of the metabolism of carbohydrates in the animal body, we may be excused from any statement of the grounds which have fully justified the award.

Professor Hill's work is perhaps less well known to the profession. Every member of it will congratulate Professor Hill, who has just succeeded Professor Starling as Jodrell Professor of Physiology at University College, London, on his recognition of his work, and will be delighted at the honour done to medical science in this country. This is the first time that the Nobel Prize has been awarded to an English physiologist, and thus the reproach is removed that the premier school of physiology has been somewhat neglected by the awarders of the Nobel Prizes.

The award of the Prize in Medicine to Professor A. V. Hill, who is a physiologist and who does not happen to possess a medical qualification, is a direct testimony to the belief that the development of medicine depends upon the foundation provided by its basic sciences. In this respect the award is peculiarly significant, for the outstanding nature of Professor Hill's work is that he has applied to the problems of physiology the mathematical methods appertaining to the more exact sciences of physics and chemistry. Professor Hill's early career gave a good indication of his future career, for in 1907 he was third wrangler at Cambridge, and later, in 1909, took a first class in physiology in the second part of the Natural Science Tripos. Similarly he first became Lecturer in Physical Chemistry at Cambridge but afterwards turned to physiology. His great work has been the accurate analysis of the processes which occur during muscular contractions. This investigation called for the most delicate refinements of experimental technique, and was carried out in the early stages on the isolated muscles of the frog. When medical men recall the weary hours they spent in their youth with the frog's gastrocnemius and an induction coil, they may possibly feel a little surprised that anything of good or importance should come from such a source, but the development of these researches has been a brilliant demonstration of the manner in which important practical results follow any increased knowledge of fundamental principles.

The progress of Professor Hill's researches has been roughly as follows:

He first made exact measurements of heat production resulting from muscular contraction, and demonstrated the

relation between the quantity of heat produced and the initial length of the fibres of the contracting muscles.

He also showed that the muscle is a machine which in the first instance has 100 per cent. efficiency, and effects the complete conversion of its potential energy to heat or to mechanical energy. The establishment of the relations between the length of muscle and the extent of heat production provided the basis for the "Law of the heart" enunciated by Professor Starling, which explains how the heart can adapt itself to different conditions, and also explains how the process of compensation in heart disease is effected.

Professor Hill next studied the time relations of heat development during muscular contraction, and found that heat production occurred during two periods; first, during the period covering the contraction itself, and then during the process of recovery. Here his work linked up with that of Fletcher and Hopkins, since it was evident that the first phase of heat production, which occurred anaerobically, was associated with the production of lactic acid, whereas for the second phase oxygen was necessary and lactic acid disappeared, so that the muscle was put back in the same condition in which it had started.

The work of Meyerhof contributed to the further analysis which showed that the glycogen of the muscle was the source of the lactic acid, and that in the recovery process between one-sixth and one-quarter of the lactic acid was oxidized, thus accounting for the heat production, while the rest of the lactic acid was reconverted into glycogen, which, on further excitation, could be broken down again to give rise to energy and lactic acid.

Professor Hill in a recent lecture declared that the final experiments in any physiological problem should always be on man, and he has followed this practice in his own researches. In studying the respiration exchanges of man during exercise he found that the process of consumption of oxygen by the muscles in man was identical with that in the isolated muscle of the frog. The presence of oxygen is not necessary for the muscular contraction itself, but since oxygen is essential for the recovery, muscular capacity will soon fail unless abundant oxygen is available for oxidizing a portion of the lactic acid and furnishing energy for replacing the muscle in a condition in which it can contract again. Thus during extreme efforts the body can work at a pace far in excess of its oxygen supply, and, as Hill has put it, the muscle goes into debt for its oxygen during violent exertion; the extent to which this debt can be incurred depends upon the amount of lactic acid which can accumulate without affecting the muscular contraction, and this quantity, strange to relate, is almost identical in the muscle of frog and man. Thus when running a 100 yards race the whole effort practically is made on credit, whereas in a cross-country race the rate at which the competitor can travel is limited by the power of the body, as regards circulation and respiration, to supply the muscle with sufficient oxygen for its current needs.

Professor Hill's researches have thus made possible a much deeper insight into the whole process of muscular activity, whether it be of heart or of skeletal muscles, and have enabled us to form a much clearer conception of the complex intracellular processes which are involved in every vital activity. These conclusions have thrown a flood of light on the conditions regulating violent muscular activity in athletics, and they form a new basis for the study of muscular fatigue. Obviously this new knowledge will be of enormous value in therapeutics—for example, it should be of the greatest assistance in the study of the causation and prevention of heart failure in disease.

Professor Hill's conclusions with regard to the fundamental laws governing muscular activity were supported by the work of Professor Otto Meyerhof, who shares the Nobel Prize. Professor Meyerhof commenced researches on the same subject independently; he studied especially the chemical processes involved in muscular contraction, and showed the nature of the reaction which provided the necessary energy for muscular contraction. His results have confirmed those of Professor Hill in almost every particular and have resulted in more accurate appraisement of the balance of the isolated muscle than would have been possible from Professor Hill's researches alone.

DECREASE OF ACUTE RHEUMATISM.

Sir, In Dr. Reginald Miller's paper on the etiology and treatment of heart disease in early life (p. 702), is the following passage referring to acute rheumatism:

"Still we may at least say that some progress has been made, but it is of considerable importance that the causes of any decrease in either the amount or severity of acute rheumatism that has taken place should be correctly assessed, for it is upon this knowledge that further action is likely to be based. Thinking, as I do, that the above statement is not correct, I feel that it should not go unchallenged.

In the absence of notification it is not easy to prove with certainty the decrease of a disease, as hospital figures for obvious reasons are not always a true guide. My own experience as house-surgeon at the Blackburn Infirmary thirty-five years ago is remarkable as showing the prevalence of this disease at that time in Blackburn and district. In the years 1888, 1889, and 1890 no less than 100 cases, mostly of a severe type, were treated as in-patients. During the years 1920, 1921, and 1922 I find from the reports that only eleven cases were admitted. I think it may safely be assumed that this disease is now less common, less severe, and is mostly confined to the poorer classes. Dr. Miller says:

"What is the underlying connection between rheumatism and poverty? This I believe to be by far the most important question yet certainly solved."

He is, therefore, of opinion that there is a distinct connection between rheumatism and poverty. The environment of the poor has during the last thirty or forty years improved enormously, by the abolition of slums and of construction of houses, at ventilation of houses, in better food and clothing, improved education, and in many other ways, so that it is the better-to-do class. This, I venture to say, is the principal reason that rheumatic fever, which is mostly a disease of the poor, has lessened both in amount and severity, although possibly enucleation of enlarged and infected tonsils may have prevented some cases and medical treatment greatly lessened the severity of others. The same improvement of environment has probably been the cause of lessened virulence of other throat affections such as scarlet fever, diphtheria, and acute suppurative tonsillitis.

The evidence seems to me to point to the fact that acute rheumatism, as in most other diseases, we shall have to rely principally on those measures which are directed against disease as a whole, and probably the greatest of these is education. It seems desirable, however, that notification should be at once adopted, not necessarily for immediate administrative action, but as the first step towards research into the environmental causes of acute rheumatism.—I am, etc.,

JAMES WHARTLEY, M.D., D.P.H.,  
Shrewsbury, Oct. 25th.  
Medical Officer of Health, Shropshire.

SPASM OF THE LARYNX.  
Sir, I regret extremely if my remarks on vertigo or spasm due to "spasm of the larynx" have in any way annoyed my old friend Dr. Peter McBride an injustice. No chapter on "Laryngeal Vertigo" can be complete without quoting his early statement that the "itus laryngis" is a syncope and not a vertigo. My remarks were necessarily limited and confined to the exposition of what I ventured to consider my own opinion. Dr. McBride's italicizing does not appear to be his, because his very plainly states that it is erroneous. Meanwhile, my old friend is quite entitled to his own opinion and I am sure he will think none the worse of me because I form mine.—I am, etc.,  
JAMES DUNDAS-GRAY.  
London, W., Oct. 25th.

that it rests on the solid basis of fact. No one who has seen the anatomical conditions which Sir Arbuthnot Lane describes as existing in cases of intestinal toxæmia can fail to recognize them, or to appreciate the results that must ensue from them.

It has been my good fortune to become convinced, by repeated demonstrations in a series of cases exhibiting various grave manifestations of intestinal toxæmia, of the existence of the anatomical conditions which Sir Arbuthnot Lane describes, and of the little short of marvellous results that have followed on the comparatively simple operative treatment which he is now practicing.

The object of this letter is to urge those who have not yet given Sir Arbuthnot Lane's teaching careful and practical consideration to do so without prejudice, and when they are convinced that it is in them, the evils that follow in the wake of intestinal stasis.—I am, etc.,  
S. HENNING BEIRAGE.  
London, W., October 25th.

CANNABIS INDICA IN SMOKING TOBACCO.

Sir, In your issue of September 22nd, 1923 (p. 521), you published an interesting memorandum on the presence of cannabis indica in smoking tobacco by Dr. R. L. E. Downer. I do not recollect having heard of any previous case of such adulteration in England. In Egypt and the East generally, as is well known, "hashish" is mixed with tobacco—chiefly cigarette tobacco—with the deliberate intention of catering for the palate of the "hashash." Tobaccoes and cigarettes so admixed with hashish are expensive and can only be purchased clandestinely. The precise object of mixing cannabis indica with tobacco for sale in England is not clear.

In regard to the analysis submitted—"0.66 per cent. of solid cannabis indica in the sample, equivalent roughly to about 1 drachm of the British Pharmacopœia tincture per ounce of tobacco"—one or two points occur to me. Assuming  $\frac{7}{8}$  minims of the tincture have been known to produce toxic effects (as your correspondent states), then to consume this amount of tincture 3.5 grams or 1/8 of an ounce of tobacco would have to be taken, equivalent to about 3½ cigarettes. I am aware that Indian hemp when smoked is much more rapid in its action than when taken internally. It would be interesting to know if the gentleman who smoked the tobacco was at all affected. There is one further point of interest to a chemist, and that is by what method cannabis indica can be so accurately estimated when present in tobacco. I assume the estimation was carried out microscopically. I am interested at the moment in the question of the relation of the Beam test to the toxicity of samples of cannabis indica and would welcome the information as to whether or not the tobacco in question gave a positive result with the Beam reaction. Indian hemp yields from 10 to 18 per cent. of substances soluble in alcohol (B.P. Code, 1922). Assuming the cannabis indica to yield 15 per cent. of extract from which the tincture was prepared, 0.66 per cent. of extract of cannabis indica would be equivalent to 1 fluid drachm of B.P. tincture, but 0.66 per cent. of solid cannabis indica would be equivalent to only 0.16 fluid drachm.—I am, etc.,

E. GIFFERTS-JONES, M.Sc., A.I.C.  
Public Health Laboratories, Department of Public Health, Cairo, Oct. 14th.

ASTHMA DUE TO INSECT POWDER.

Sir, With regard to the case of asthma due to insect powder, recorded in your issue of October 27th (p. 764) by Drs. Garatt and Bigger, it would be most interesting to know (1) whether the patient was sensitive to dog hair, for dogs enter largely into the history of her attacks, and (2) whether the insect powder was tested on a normal arm as well as the patient's. I think this should always be done when a reaction is obtained to a new drug; so many articles give reactions on everybody's arms—notably is this cause of the asthma of one of my patients, it gave just as large a reaction on my own arm.—I am, etc.,  
FRANK COKE.  
London, W., October 28th.

## VACCINATION PROPAGANDA.

A FEW months ago (July 14th, p. 72) we devoted some space to the present position with regard to vaccination propaganda, and called attention to the excellent little tract expounding the value and importance of vaccination issued by the Ministry of Health.<sup>1</sup> The paper by Dr. Killick Millard published on September 29th leads us to recur to the subject, as he raises certain matters not dealt with in our earlier article. Dr. Killick Millard stated that in 1906-20—a period, by the way, of fifteen and not sixteen years—"even the registered deaths from vaccinia amounted to 165, and it has recently been admitted, in answer to a question in Parliament, that by no means all the deaths due to sepsis following vaccination are debited by the Registrar-General to vaccinia." We have thought it well to make inquiries of the Registrar-General's department, and learn that the 165 deaths included every case in which sepsis or erysipelas following vaccination was mentioned in a death certificate. Not only so, but the 165 deaths also included cases of such diseases as bronchitis, pneumonia, diarrhoea, mentioned as following vaccination. Indeed, the practice was to debit the death to vaccination unless correspondence with the certifying practitioner—as occurs occasionally in connexion with certificates of doubtful meaning—made it clear that he did not regard the vaccination as in any way a contributory cause. Of the 165 deaths, 92 occurred in the eleven years 1910-20, and this 92 included only 41 attributed to "vaccinia"—and that term, as used in the Registrar-General's reports for these years, included much more than the rare condition sometimes described pathologically as vaccinia or general vaccinia.

It seems desirable to make clear the whole position with regard to such cases. In 1911 the classification of deaths in general was modified in this country, owing to the adoption of the international list of causes. This involved substitution of the class "Vaccinia" for the old class "Cow-pox and other effects of vaccination." At the same time occasion was taken to revise the entries in the class. It was deemed best to continue to ascribe to vaccination cases where it was mentioned in certificates of death from diseases like those named above—bronchitis, diarrhoea, and so forth. But in respect of sepsis or erysipelas there had always been a want of uniformity which it was thought right to rectify. Where sepsis or erysipelas followed an insect bite, or any scratch or slight puncture or abrasion of the skin, the death had always been attributed to sepsis or erysipelas as the case might be, and not to the trivial lesion which had given opportunity for the infection. But where that lesion chanced to be a vaccine vesicle the death had been set down to vaccination, and it was necessary, in accordance with the international list, to correct this anomaly by classifying any such death as due to sepsis or erysipelas just as in other cases. The change generally was explained in the Registrar-General's report for 1911.

That, however, is not all. For purposes of comparison the Registrar-General in his annual reports gives in respect of every separately tabulated cause of death the figures for a series of previous years. To continue this practice a kind of double entry was required for the years 1911-20, wherever the classifi-

cation had been changed. Besides the new entries under vaccinia, the old entries under cow-pox and other effects of vaccination were given in a retrospective table, and it was only in 1921 that the double entry could be dropped. But a paragraph in the text of the report for 1921 gives the information which will enable anyone to transfer such deaths to the vaccinia column, so that the opponent of vaccination can add what he pleases to the Registrar-General's table. Regarding 1921 the present Minister of Health, Sir William Joynson-Hicks, in answer to a question in Parliament by Mr. Snowden, said that "vaccination" was mentioned on 7 certificates of death and "general vaccinia" on one. They were classified as follows: 3 due to vaccination, 3 to erysipelas, 2 to purulent infection, septicaemia.

We may take this opportunity of referring to another point in Dr. Millard's article. In writing of the attitude of the medical profession he asserted that when the conscience clause was proposed "we opposed it for all we were worth," and "we said it would result in a further neglect of vaccination." Dr. Millard's "we" is not a precise expression, and we desire to point out that it does not include the British Medical Association; far from opposing the conscience clause "for all it was worth," the Council of the Association was prepared to accept the clause, if only the law and the clause were to be applied not merely to infant vaccination, but to revaccination, which ought to be legislated for like infant vaccination. That was the official attitude of the Association, and the adoption of its proposal would have got rid of the anomaly of legislative pressure being applicable only to primary vaccination, though revaccination is also required for continued protection against small-pox. Moreover, domiciliary vaccination was begun along with the operation of the conscience clause, and Dr. Millard is mistaken when he asserts that "a further and serious decrease in vaccination followed." On the contrary, the percentage of vaccinations to births, which had fallen to 62.4 in 1897 and to 61.0 in 1898, began to rise immediately, and continued to be over 70 per cent. (in one year 75.8 per cent.) until the baleful Act of 1907 took effect. That Act was at once followed by a decline in infant vaccination, which has continued ever since.

Most fortunately for the public welfare the type of small-pox in this country, as is well known, has commonly in recent years been mild. This has done much to avert the punishment which would have followed the neglect of vaccination had the European variety of the disease continued to prevail. Gloucester and Leicester have been amongst the principal beneficiaries, though far from frankly appreciating their good fortune. Even 38 per cent. of infant vaccinations, as in 1921, is, however, much better than nothing, and the profession would be falsifying its whole position by giving any countenance to Dr. Millard's suggestion for repeal of all obligation towards vaccination, on the hypothesis that thereby, when epidemic small-pox reappears, vaccination would be more readily accepted by the public. Parliament may do what it likes and the consequences will be on its head. The medical profession can have no part in such political opportunism, and the newly improved administration of the existing law is welcomed as an indication of the present Government's recognition of its duty to the helpless infants who are allowed to run the risk of small-pox, mild or severe, owing to the indifference of their parents.

<sup>1</sup> Reports on Public Health and Medical Subjects. No. 8. Small-pox and Vaccination. H.M. Stationery Office. 1921. Price 3d. net.

Kilburn). The firm will place at the disposal of purchasers of cars, through the Medical Insurance Agency, their system of deferred payment; a purchaser pays 25 per cent. of the value on delivery and the balance by monthly or quarterly instalments as desired. An addition of 2½ per cent. to the list price of the car is made to cover interest charges. The company has a stand (No. 129) in the Coach Building Annexe of the Olympia Show, and its representatives will be prepared to give advice free of charge to medical men intending to purchase on the advice of the Medical Insurance Agency. Application for an introduction should be made to the Secretary of the Agency, 429, Strand, London, W.C.2. It appeared from the balance sheet of the Medical Insurance Agency for the year 1922 that a sum of over £2,000 had been returned by way of rebates to those insured through the Agency, an increase of £367 over 1921. The surplus carried to the Medical Benevolent Fund was slightly larger in 1922 than in the preceding year, and a sum of £1,500 was allotted as follows: to the Royal Medical Benevolent Fund Guild £630, to the Royal Medical Benevolent Fund £315, to the Epsom College Benevolent Fund £210, to the Royal Hospital and Home for Incurables, Putney, £52 10s., the *Lancet* Editor's Discretionary Fund for dealing with emergency cases £25. A further sum of £267 10s. was set aside for the fund established by the Agency to make grants in aid of the education of girls, orphans of medical men, or daughters of unfortunate brethren who are precluded by age or ill health from continuing to practise. Including the contributions now made the total sum subscribed to medical charities by the Medical Insurance Agency since 1910 exceeds £11,500.

#### THE HEALTH OF THE SCHOOL CHILD.

SIR GEORGE NEWMAN's report for 1922 as Chief Medical Officer of the Board of Education has been issued this week. It contains twelve chapters. In an introduction he gives a general review of the situation and observes that in spite of the restrictive effect of the policy of public economy the year 1922 was not a time of reaction. Though the new weapons for the warfare against disease and neglect amongst school children could not be used to the extent intended, the scheme remains intact and ready for fuller application whenever circumstances permit. Ten years ago the only statutory obligations in connexion with medical services were the medical inspection of children in elementary schools, and special education for the blind and deaf. Medical treatment was purely optional, and so was the provision of special schools for the mentally and physically defective. Now treatment as well as inspection is obligatory, and it is the duty of every education authority to make comprehensive provision for all abnormal children. Some authorities, however, are behind-hand, and the inequalities between various areas must be reduced gradually and a minimum standard everywhere attained. The pause in expansion has been utilized by the Board to determine the general nature of future development. The standards of abnormality, which at present vary in different areas, must be investigated and harmonized, though due provision of special schools for the defective is expensive. It costs about £12 a year to educate a child in a public elementary school, £30 in a day special school, and £90 in a residential school. But knowledge of the causes and methods of prevention and treatment of fundamental defects is extending, though there are not yet accepted and reliable standards of mental defect. Reference is made to the widely different practice of different authorities in respect of requiring payments for medical treatment from parents, and the Board has had to take action. Free treatment must now be definitely restricted to the necessitous, though this may diminish

attendances where no fee had hitherto been exacted. The organization of physical training in elementary schools has made good progress. The fundamental points are that the work of training should be carried out by the teachers themselves, who should from time to time have special assistance and guidance from experts. The great value of good work is testified by quotation from Dr. Wheatley, county medical officer for Shropshire. Unfortunately, skilled training organizers are few, and the cost of their services is apt to deter local education authorities from making such appointments. Meals for school children involved a very heavy outlay in 1921 owing to the coal strike, and much attention was given to limitation of expenditure in 1922. Sir George Newman, however, is satisfied, as a result of certain careful inquiries by school medical officers, that in spite of unemployment the nutrition of school children was not below the pre-war standard, and in some cases was appreciably higher. The most urgent questions awaiting solution are said to be the further co-ordination of the school medical work with the public health service, attention to the physical condition of children under 5, and effective education of the dull or backward child. The importance of a comprehensive scheme for the treatment of dental defects is recognized, as is the systematic organization of the teaching of hygiene and physical training. We hope in an early issue to deal further with this interesting report. It is published by H.M. Stationery Office, price 1s. 6d., and can be obtained through any bookseller.

#### POST-GRADUATE WORK IN MELBOURNE.

UNDER the auspices of the Melbourne Permanent Committee for Post-Graduate Work, regular general and special courses for graduates are arranged every year. The committee is composed of representatives of the Faculty of Medicine, the Council of the Victorian Branch of the British Medical Association, the Walter and Eliza Hall Institute of Research, and the metropolitan general and special hospitals. The courses arranged by the committee, for which Dr. J. W. Dunbar Hooper and Mr. Harold Dew are the enthusiastic honorary secretaries, have been signally successful. No better evidence of the attractive nature of the work provided could be furnished than the fact that a number of graduates have journeyed regularly from remote parts of Australia to attend the classes. The most recent attraction organized by the Melbourne Permanent Committee for Post-Graduate work was a series of four lectures on disorders of nutrition delivered by Professor C. J. Martin, F.R.S., Director of the Lister Institute, London, who was visiting Melbourne as a delegate to the Pan-Pacific Science Congress. The Permanent Post-Graduate Committee is endeavouring to establish a fund by means of which it will be able to obtain the services of distinguished leaders in research whose work will furnish not only instruction but a stimulus to medical men to keep up to date. By great good fortune Professor Martin was available as the first lecturer under this scheme. At the same time Professor Martin's visit to Melbourne afforded great pleasure to many of his old friends and former students. As professor of physiology in the University of Melbourne, and later in close association with the Australian Army Medical Corps during the war, Professor Martin made many enduring friendships in Australia.

#### ALCOHOL TAXATION AND DELIRIUM TREMENS IN DENMARK.

EACH of the four Scandinavian countries is at present conducting different legislative experiments in the control of alcohol consumption. While one country rations the supply of alcohol, another attempts to enforce prohibition, and a third—Denmark—attempts to encourage sobriety by

begun that the first case of dysentery occurred. Blood specimens implicated the farmer and his foreman, but even before the cause of the outbreak was definitely established the farmer had voluntarily withheld the sale of his milk, a praiseworthy instance of intelligent and disinterested co-operation. The number of households ultimately affected was 11, and of the 18 cases 13 were below the age of adolescence. Multiple cases occurred in 5 households, and case-to-case infection may have operated. The outbreak was of long duration, and the period during which one of the two men implicated was presumably a carrier of *B. dysenteriae* was of unusual length. He had been invalided from the army in 1918 after suffering in the East from symptoms suggestive of dysentery, and had not since suffered from diarrhoeal disease. The bacteriology of the outbreak is reported in careful detail by Mr. Bruce White. Both *B. dysenteriae* Flexner and *B. dysenteriae* Shiga were found. The presumption would seem to be that Shiga cases in children occurred before the investigation and were fatal, while the Flexner infection did not cause severe symptoms in adults. Dr. Falkner, the medical officer of health, took an active part in the inquiry, and had already set on foot bacteriological investigation before the central authority was called in.

#### INSULIN BY THE MOUTH.

It has been advised that insulin should be given by subcutaneous injection to diabetic patients on the ground that it does not produce any effect when given by the mouth. Dudley and others have proved that insulin is rapidly destroyed by pepsin and trypsin *in vitro*. It is probably for this reason rather than the failure of insulin to pass the intestinal wall that the administration of pancreatic extracts by the mouth has been relatively ineffective. There is evidence that insulin may be absorbed from the stomach when given in alkaline solution, the effect of the alkali being not to neutralize the acid but to inactivate the pepsin. Large doses of insulin would appear to be necessary to produce any effect. It is known that water is not absorbed from the stomach, but that alcohol is. This suggested to L. B. Winter that the administration of insulin by the mouth might be more successful if it were given in weak alcoholic solution. He has recorded in the new number of the *Journal of Physiology* certain experiments on the rabbit. The insulin was dissolved in 15 to 25 c.cm. of 20 per cent. alcohol, warmed to body temperature, and administered by the stomach tube. In the first experiments large amounts of insulin or yeast extract were used, with the result that the blood sugar quickly fell to the convulsion point. It was evident, therefore, that the insulin must have been rapidly absorbed from the stomach. Smaller quantities of insulin were then used, and it was found that the amount of blood sugar was reduced, although convulsions did not actually occur. It is well known that the response of different animals to subcutaneous injection of insulin varies, and this is a source of uncertainty in the testing of preparations. Still greater uncertainty must attach to experiments in which the extract is given by the mouth, but the blood sugar values are held to show that the effect of insulin on animals is similar, whichever method be used. If large doses were given the blood sugar was reduced very rapidly; if small doses the fall and rise were both slower, but the action of insulin given by the mouth was not delayed. That the alcohol was responsible for the absorption of the insulin was shown by a control experiment in which insulin dissolved in normal saline was given by the mouth. No effect on the blood sugar was observed. The conclusion is that insulin in weak alcoholic solution, administered to rabbits by the mouth, causes the blood sugar to fall to a low level. We gather that the investigation has not yet been extended to man.

#### THE GARDNER COLLECTION AND LONDON MEDICAL TOPOGRAPHY.

FROM November 12th to 16th next there will be dispersed at Sotheby's, New Bond Street, the second portion of the great Gardner collection of London topography which is said to include altogether more than 50,000 prints, drawings, etchings, and other illustrations of old London. The items of medical interest disclosed by the catalogue may quite possibly omit many which a detailed examination of the parcels themselves would reveal; for many of the lots include twenty, thirty, or even forty items, only one or two of which are specified by the catalogue. Among those which are, however, thus distinguishable may be mentioned the following: the old Chelsea Physic Garden, of which there are apparently many different views; and Chelsea Hospital, of which there are even more; John Hunter's house at Earl's Court (where the District Railway station now stands); St. George's Hospital, of which there are several views, including the rare print by J. Ware; the Lock Hospital in Grosvenor Place, with a portrait of Daniel Lock; Windmill Street—the catalogue does not say whether this shows the Anatomy School for which that thoroughfare was famous. Golden Square, probably antedating the time of the Throat Hospital, is shown in a rare engraving by Nicholls and in other items. The interior of an old "doctor's shop" in Walker's Court is another from the same district in Soho. One of the lengthy series connected with the Covent Garden neighbourhood shows "Dr. Rock, Dr. Bossy, Martin Vanbutchell and other Quacks." Clare Market, Portugal Street, and (old) King's College Hospital make up three lots, including together forty-three items. The College of Surgeons in various views and portraits of celebrated surgeons—twenty-three items in all—are to be sold in one lot. Westminster is copiously represented in the sale, but the catalogue does not indicate whether any views of the Westminster Hospital are to be found. Nor does the Charing Cross section allude to either of the hospitals now situated there. The College of Physicians is listed with various other views of Pall Mall East and Whitcomb Street. The collection is to be on view to the public three days before the sale opens.

#### CLEAN MILK.

A PAMPHLET on clean milk has been published recently by the Kent Milk Recording Society; it contains a full report of the first clean milk competition held by it last spring in conjunction with the Kent Education Committee. The four purposes of this competition were as follows: (1) to show that there was already available a supply of clean milk in the county in addition to that sold as Grade A and as certified milk; (2) to assist dairy farmers by milk examinations and by advice as to possible improvement of their methods; (3) by means of a friendly rivalry to stimulate both the dairy farmers and their milkers to greater interest in the production of clean milk; (4) to demonstrate how reasonably clean milk can be produced under ordinary farm conditions, and without excessive increase of cost. The competition included the examination of samples of milk (chemical analysis and the investigation of the bacterial content and keeping quality), and inspections of the farms with especial reference to the health of the cows, the general equipment, and the methods of milking, cleansing, and so on. Each of the fifty-three competitors sent in samples of milk at fortnightly intervals, and, although licensed purveyors of certified or of Grade A milk were not allowed to compete, yet out of the 225 samples that were examined no fewer than 212 came up to the Grade A bacteriological standard, and 109 samples were actually within the standards of certified milk. These results certainly demonstrate the high quality of the milk.

## British Medical Association.

## THE COUNCIL DINNER.

THE second annual Council dinner of the British Medical Association was held in Edward VII's Rooms, Hotel Victoria, on October 24th. Dr. R. A. BOLAM, Chairman of Council, presided over a company of 200, and had on his right the chief guest of the evening, Sir Dawson Williams, Editor of the *British Medical Journal*, whose twenty-five years of editorship the dinner was designed to commemorate; and on his left Sir W. Joynson-Hicks, M.P., Minister of Health. The others at the principal table were:

The Right Hon. Lord Justice Atkin, Sir John Atkins, Dr. T. W. Naylor, Sir John of Medical Officers of Health, Sir John of the Royal College of Surgeons, Dr. H. J. Rear-Admiral J. Chambers (Director-General of the Royal Navy), Mr. C. P. Childs (President of the Association), Sir John Collyer, M.P., the Right Hon. Sir Henry Craik, M.P., the Right Hon. Lord Dawson of Penn, Sir W. Hale-White (President, Royal Society of Medicine), Sir Laurence Halsey, Dr. R. Wallace Henry, Dr. A. Bostock Hill (President, Association of County Medical Officers of Health), Lieut.-General Sir W. B. Leishman (Director-General, Army Medical Service), Sir Edwin Lutyens, R.A. (architect of the Association's new building in Tavistock Square), Dr. J. A. Macdonald, Major-General Sir William Macpherson, Sir Philip Magnus, Sir George H. Makins, Dr. L. G. S. Molloy, M.P., Air Commodore D. Munro (Director R.A.F. Medical Service), Sir George Newman (Chief Medical Officer, Ministry of Health), Sir Alfred Rice-Oxley, Sir Arthur Robinson (First Secretary, Ministry of Health), Sir Leonard Rogers, Sir Humphry Rolleston (President, Royal College of Physicians), Sir S. Russell-Wells, M.P., Major-General J. B. Smith (Medical Adviser to the India Office), Sir Squire Sprigge, Sir Charters Symonds, Mr. E. B. Turner, Sir Jenner Verrall, and Dr. T. Watts, M.P.

## THE COMMON HEALTH.

Mr. C. P. CHILDE proposed "The Common Health." He spoke of the great advances made in recent years in preventive medicine, and in particular the enormous reduction in infant mortality. Thanks largely to sanitary science, which might be said to have begun in 1840 with the appointment of the Poor Law Commission to inquire into the high incidence of disease and the high mortality among the poorer classes of the community, the toll exacted by some common diseases had been greatly lessened, and some, like typhus, had become extinct. He quoted some cogent words from Lord Palmerston, who, as Home Secretary, was petitioned in 1853 to appoint a national religious fast with a view to averting an anticipated outbreak of cholera:

"It did not appear to Lord Palmerston" (the then Home Secretary wrote) "that a national fast would be suitable to the circumstances of the present moment. The Maker of the universe established certain laws of Nature for the planet on which we live, and the weal or woe of mankind depends upon the observance or neglect of those laws. Lord Palmerston would therefore suggest that the best course which the people of this country can pursue to deserve that the future progress of the cholera should be stayed would be to employ their time planning and executing measures by which those portions of their towns and cities inhabited by the poorer classes may be freed from those causes of contagion which if allowed to remain will be fruitful in death and disease in spite of all the prayers and fasting of a united but inactive nation."

The real function of health authorities was to remove those conditions which made ill health inevitable, and the first of these was the slum areas which disgraced the great industrial cities. A healthy home was the very basis and foundation of the common health. To build up a country of healthy homes was a gigantic financial and sociological proposition, but it could be done by a bold and imaginative statesmanship. (Applause.) On the publications of the New York State Health Department there occurred this heading: "Public health is purchasable. Within its natural limitations every community can determine its own death rate." This had been abundantly proved during the past generation as a result of sanitary legislation.

Sir WILLIAM JOYNSON-HICKS, in responding, said that the Minister of Health was at all times assured of a welcome from the British Medical Association. They and he were concerned with the question of public health—they with a profound knowledge of the subject, he with but little. At the same time, in this curiously constituted world, it was

the man who knew little about the subject (although advised by those who knew much) who had the last word. He went on to speak of the value of public health to the nation. In twelve months, among the insured population alone, 19½ million weeks of work had been lost by reason of sickness; 50 per cent. might be added for the workers not insured, bringing up the total to 30 million lost weeks of work, representing, at an average of £2 a week, £60,000,000. If that could be brought down by one-half it would mean a great addition, not only to the happiness, but to the financial well-being of the country. Then there was the wastage from premature deaths. Every man, by the time he had reached 21, had cost the community something like £400 in food, housing, clothing, and education, and the mortality from preventable disease meant that numbers of the population were cut off before they could make any return for this expenditure. The State and the practitioner must work together. ("Hear, hear.") There must be mutual understanding and co-operation. The Ministry of Health was the machinery which endeavoured to co-ordinate the work of the public health departments and of the private medical practitioner. "We are imperfect, but if we were not imperfect there would be no room for that expert and independent criticism to which the proposer referred and to which, I am bound to say, I am not a stranger. Any man in public life who objects to honest criticism is either a fool or a knave." He reminded the company that, great as had been the advances in preventive medicine, there still remained unconquered scourges. In dealing with these the Minister of Health was helpless without the medical profession and its gallant band of investigators. A great deal of his own work was purely administrative, but his dream as he sat in his chair at the Ministry was of wider discoveries and an enlarging compass of knowledge, bringing hitherto baffling diseases into subjection. He had been but a few weeks in his present position; he came to it with great ideals, but those ideals had grown every day, and he believed that great as had been the accomplishments in public health during the last fifty years the future would eclipse them all. (Applause.)

Sir WILLIAM HALE-WHITE referred to the remarkable altruism of the medical profession, whose quest for the common health was in defiance of its own interests. The secret of business was to create a demand; the medical profession existed, not to create a demand, but to spoil it. It was constantly stamping out the very diseases by which it lived. This had always been characteristic of the profession. In the early days the functions of priest and doctor were combined in one individual. The priests of Egypt made cats sacred because the cats killed the rats that caused the plague, although the plague unchecked would have brought large sums of money to those practising medicine. In Leviticus xiii and xiv there was described a disease called indifferently leprosy and plague, evidently a highly infectious disease, and all the instructions were directed to stamping out the very source of the doctor's income. The man affected had to be separated from his fellows, his clothing burned, his house (if it had harboured several cases) pulled down and its stones scattered. Coming down to the days of Edward Jenner, the speaker told the story of how, when all other pleas to Napoleon had failed to secure the release of two students in Geneva, Jenner added his request, and Napoleon's reply was, "We can refuse nothing to that great man." Coming to our own day he instanced the putting down of malaria and typhoid—in both cases thanks to the researches of Englishmen—although the profession was thereby doing the most unbusinesslike thing in its own interests that could be conceived.

## "OUR EDITOR."

The CHAIRMAN said that the occasion of the dinner was one of which they in the British Medical Association were proud. The chief guest that evening was the Editor of the *Journal*, and before calling upon Sir John Bland-Sutton to propose his health he would read two telegrams, one from Sir John MacAlister, whose doctor forbade his attendance, and the other from Dr. Guy Stephen, who was associated with the *Journal* for many years, and who had

d) which had worked very well ever since, and had of ethics and a control over its members such as, ght, Lord Justice Atkin would allow him to compare o very efficient discipline maintained by the Bar. use.) The conception of the *Journal* which was the Council, and which he believed to be a true ion, was that it should be at once a newspaper ientific organ. It was not always easy to meet those ditions. The progress of science was so remarkable s a reviewer said of a voluminous author, they ed after" the writers of scientific papers in vain. ould read an extract from the very illuminating spiring Harveian Oration which Professor Starling ed the other day:

el that I have had the good fortune to see the sun rise on ed world, and that the life of my contemporaries has coin t with a renaissance but with a new birth of man's powers environment and his destinies unparalleled in the whole of mankind."

actly expressed what had been his own fortune in to that side of the *Journal's* activities. That had ally the most important part of his life-work, as it be the most important part of the work of his ne, Dr. Horner. (Applause.)

onclusion, he would like to congratulate the Council e series of dinners. In the past perhaps they had o businesslike, and had forgotten the advantages of amenities. He was glad to think that this time next ere was a prospect of the Council holding its dinner Association's own dining-room in its own house in bury, which was already the home of many institu- e learning, and bade fair to become the university e of London. The building was a beautiful example estic architecture, the work of a great imaginative ir Edwin Lutyens, who had honoured the Associa- ith his presence that evening. They were greatly ed to the Chairman, Dr. Bolam, for the trouble taken in the matter of the building. (Applause.) o was any difficulty in naming the house he suggested ht be called "Bolam's Buildings, Bloomsbury" l ter.) No dinner table was complete without some plate upon it. If then the Council was to dine, and in guests at its own table, it seemed imperative should have some silver, and he had ventured to with him that evening a very small beginning. The r. Francis Fowke, who during his thirty years as ial Secretary had worked a most satisfactory change finances of the Association, had sometimes to record, anded, the minutes of Council meetings; he was in bit then, and only then, of taking an occasional f snuff to keep his attention alert when he found it g. The speaker did not wish to suggest that any rtificial stimulus was needed nowadays either by the en and members or by the Secretaries, nevertheless ed the Council would accept from him, as a beginning ir collection of silver plate, a snuff-box, which he d to the Chairman amid applause.

CHAIRMAN accepted with many thanks this very ul gift as the first item in the Association's collec- silver plate. He added that he had already offered a to the Minister of Health. (Laughter.)

### "OUR GUESTS."

CHAIRMAN proposed the health of the guests. tage was usually taken of a dinner such as this to our to retiring officers, but no officer of the Asso- who was retiring was able to be present that g; Sir William Macewen, the Past President, was t moment nearing the shores of Australia, if he had eady landed. The Council was very proud that so distinguished members of the profession, not specially ed with the political activities of the Association, ave assembled that evening to do honour to their guest. In Sir Dawson Williams they had, not, as litor sometimes asked them to believe, an archaic ul, but a physician who had not lost touch with the development in his science, a man who exercised an ee wider than many of them dreamed, and one whose dled literary ability was an inspiration to his staff.

(Applause.) It must not be assumed that his sole occupation was his beloved *Journal*. Those in the offices of the Association had always found that he was what the old preacher termed that "medicine of life," a faithful friend. (Applause.) Dr. Bolam then went on to welcome in grace- ful phrases the titular heads of the medical services of the Navy, Army, and Air Force, and the Presidents of the two Royal Colleges. He coupled with the toast the names of Sir Humphry Rolleston, who was one of the greatest friends the Association ever had, and Lord Justice Atkin, who had given repeated evidence of his kindly feelings towards the medical profession.

LORD JUSTICE ATKIN caused much laughter by his descrip- tion of an obscure disease the title of which he thought at present was not thoroughly well known. It began with a sense of shock, following upon the intelligence that the patient was expected to make a speech, followed by depression, failure of appetite, excitement at the crisis, occasional in- coherence, sometimes aphasia in an extreme form; at other times the symptoms succeeding the crisis were different, the patient becoming talkative, sometimes exhibiting delu- sions, with signs of megalomania, and a marked inability to resume a sitting posture. The symptoms sometimes yielded to mild alcoholic treatment, and in course of time abated. His own claim to speak on that occasion was that he belonged to a small society (the Medico-Legal Society), composed of the members of both professions, in which each derived benefit from association with the other. The society dealt with a great many topics, and occasional echoes of its proceedings were to be found in the *British Medical Journal*. The medical profession quite properly prided itself upon its success in preventive directions, and the ideal of the lawyer was not very far removed; it was not to foment strife, but to abate it. Very few laymen were aware of the extent to which the ordinary legal practitioner acted as a peacemaker. In the legal profession also some- thing was done towards relieving the legal necessities of the poor, but the contribution was small indeed in comparison with that which was made by the medical profession in a similar respect. There was no profession which showered such gifts upon the public.

Sir HUMPHRY ROLLESTON said that he responded, not only as a private person, but as President of the Royal College of Physicians, and in that dual capacity he cordially expressed the best wishes for the progressive and assured prosperity of the wonderful organization of the British Medical Association, which now numbered 26,000 members, or more than half the registered medical practitioners of the Empire. Though well established in years, the Associa- tion was ever finding new avenues of activity, and with the enthusiasm of healthy vigour was anxious to go on and conquer new worlds. Indeed, the complexity of the Asso- ciation's activities was somewhat bewildering; with new legislative measures the political responsibilities imposed on it had multiplied. Founded at Worcester in 1832 by Sir Charles Hastings with the object of promoting medical science and maintaining the honour and interests of the medical profession, it continued admirably to uphold its tradition of representing the whole country, as was shown by a glance at the list of its leading officers; though its headquarters were in London it was in no way metropolitan, and it took the broadest views. Devoted to the welfare of the profession and to the object of uniting its independent units into a combined force—no easy task—it exercised political and ethical and professional functions. After years of patient work it was instrumental in passing the Medical Act of 1258, and since then the increasingly numerous legislative procedures touching medical men and matters had been thoroughly scrutinized, criticized, and influenced by the special Committees of the Association. Its educational scope, including the Annual Meeting, was equally large, but he would refer only to the Library, the Science Committee, and the *Journal*. The Library was a most important part of such an organization, and with the recent appointment of Mr. W. G. Spencer as honorary librarian it was certain that the Library in the new building would be a leading feature, run on the most modern and efficient lines, and thoroughly worthy of this great organiza- tion. The Science Committee distributed funds for re-

Tumours in hollow viscera can excite them to action.

HABITS (ECOLOGICAL) OF TUMOURS,  
 DELIVERED TO THE CAMBRIDGE UNIVERSITY MEDICAL  
 SOCIETY, NOVEMBER 7TH, 1923,  
 BY  
 SIR JOHN BLAND-SUTTON, B.R.C.S.,  
 CONSULTING SURGEON TO THE MIDDLESEX HOSPITAL.

THE HABITS (ECOLOGICAL) OF TUMORS.

"Tumors" which attempt to denude the term "tumor" applicable to a hotbed of morbid conditions. A mouse is a mammal, so is an elephant—they have features in common. Many morbid conditions called tumors have significant features in common which permit them to be classified for descriptive purposes, for clinical study, and for treatment, but in size and habits they vary as much as mice and elephants.

Tumors are of importance to surgeons because of their harmfulness to the individuals on whom they grow. Nearly all make life uncomfortable; many shorten life. Surgeons do their best to get rid of them and study their habits (ecology) in order to acquire increased proficiency in this respect.

The microscope taught us that the tissues of tumours do not differ from those normal to the body, and with the assistance of embryology the investigation of tumours has become for many an unattractive study. Embryology has provided the key to many pathological riddles. I vainly attempted to help it in its task to solve the problem of the origin of tumours, and a large part of my leisure for many years was devoted to this quest.

I shall now show how the life history of a tumour corresponds with that of the parent organ. Tumours pass through a period of growth, attain maturity and in some instances exercise the same function as the parent organ; and this exercise by increasing their bulk leads to their discovery. The statement that tumours exercise no function is grossly erroneous.

The tissues of tumours do not differ in their habits (ecology) from the normal tissues of the body.

Take, for example, hyaline cartilage. When this tissue assumes the form of a tumour it is naked-eye and microscopic characters are identical with normal cartilage. It often calcifies, and becomes converted into bone. Like cartilage, the articular end of a bone, it may be smooth and glistening; it is submitted to friction and a synovial membrane forms over it, constituting a gliding capsule; the space enclosed by the capsule may become distended with synovial fluid. Many instances are known in which a bursa is thus kind, formed over an exostosis, has contained loose bodies in every respect resembling the familiar joint-mice of normal articular cavities. Exostoses of long bones repeat the phases of development common to such bones, and like an epiphysis; the growth of the exostosis ceases with that of the skeleton.

Composite tumors are of two kinds, the benign and the malignant. The benign tumors are derived from the germinal cells and grow in silence. In due time they establish a relationship with the surrounding tissue, and the tumor manifests its well-being of the gum and pain such as accompanies the erupting. These troubles lead to its discovery, which usually ends in its extraction. Some superficial tumors grow out of the tooth and are taken out by the natural process of eruption, for the tumor may fall out with the normal teeth and be replaced and taken out in the same way as the normal teeth. This has happened to men and horses.

and on turning over the later pages of Ireland's history there were found, after the lapse of a hundred years, evidences of a restoration to its former position, in the names of Colles, Graves, Stokes, Corrigan, Butcher, Tuffnell, and many others. In recent years Irish surgeons and physicians had been engaged in a heart-breaking struggle in their efforts to advance, for the ideals of medical men were different from those of politicians. They of the College of Ireland were trained to be realists, and their optimism extended to a profound belief in their country, and that the ship of State would ultimately be steered into peaceful and happy channels.

Few institutions in Ireland could claim such a record as theirs, of having existed for over a hundred and forty years; and if it was asked how it was that their College had survived in a robust condition through the storms of the past and present would answer, that it had always been content to attend strictly to its own business. Since the College ship was chartered by King George III on March 9th, 1784, their pilots steered for surgical progress without deviation. Storms might have caused anxiety, but the ship's course had never been deflected by so much as a single degree; and of politicians, in the mischievous sense, they happily had none in the College of Surgeons in Ireland. America had taught them the value of self-reliance; they had felt the influence and had been stimulated by the example. He brought them fraternal greetings from the medical profession in Ireland, with the hope that the unexampled progress and prosperity of their country might continue in unabated vigour.

## Nova et Vetera.

### DOCTORS ON THEIR OWN ACCIDENTS AND ILLNESSES.

BY

THE LATE DR. J. W. BALLANTYNE OF EDINBURGH.

References were made recently\* to the sale of Sir Robert Sibbald's library, and to its remarkable contents—names, many of them, which would excite brisk competition in a modern auction room. This distinguished Edinburgh physician of the end of the seventeenth and the beginning of the eighteenth centuries showed a curious interest in all the details of the various accidents which happened to him, and in the illnesses from which he suffered. Several instances were found in his autobiography (first published in 1833), with engagingly frank disclosures of what occurred to him, and numerous conceptions of his wives, for he was twice married. Here is his narration of a golfing misadventure:

"No accident befell me on the 16th of October, 1690, that as I was coming from Sir Robert Milne his house in Leith, where I had been visiting his good brother Mr. Elphinstoun's wyfe, who had taken physic that day, about four afternoon, as I was going to pass the ditch to goe to the Links, when I left some money playing at goulfe, and my servant following me, neither I, nor the boy, adverting, I was stricken by a boy (said to be Captain Taylor his son) of fourteen or fyfteen years, with the butt of the club, with much force, betwixt the eyes, at the root of the nose."

The wound is described with meticulous exactitude, for it is not Sir Robert's own wound, so that all the details were important and suitable to be recorded?

The wound was oblong, large, and about half ane inch long. It was about half ane inch above the cartilage of the nose. The parts about the right eye was [sic] livid, and both the canthi majores were swelled. I bled much, and took a coach and came up, and good while before I could want [that is, do without] a plaster to it. It was God his great goodness that neither the cartilage of the eye, nor one of the eyes put out, for it was done with the sharp butt of the club."

An instance from more recent times may be quoted in which another doctor also dwells with full descriptive minuteness upon an ulcerated sore throat. Dr. John Brown, the author of the never-to-be-forgotten sketch, *Myself and my Friends*, and of the delightful *Horae Subsecivae*, who suffered; the story was told in a letter to his brother James—the place again was Edinburgh, and the date 1838.

"Well, when down at the Terrace on Friday night (September 18th) writing to Andrew, I felt my throat turn suddenly sore and couldn't get difficult, went home, couldn't sleep, got up, could not go out, frequent pleasant creepings over me, went into the Infirmary, worse of this, all the blood inside, fought with it till 3, went home to bed, and sent for Sandie Peddie; no sleep Sunday going on worse and worse; no sleep. Monday desperate, getting afraid about myself, at twelve noon sent for him, who looked very glum, six leeches had been put on on

Sunday, mustard, etc., no sleep. Tuesday, throat ecstasically painful, pulse very quick, all the time headache very bad, alternately in badness with the throat. On Tuesday afternoon, 12 leeches behind the ear, no better, bran poultices everlastingly, no good. Sent for Scott at 12 at night. He bled me to more than 16 ounces, with instant relief, how delicious! nothing in the world like it. He is a wise wight that Scotus. He went off; a quiet but sleepless night, throat still very sore. Scott and Peddie saw me about 7. I told them I was sure ulceration had begun; so it had with a vengeance, a hole I could lay my thumb in on one side, and a smaller on the other. Nitrate of silver liberally applied. Dr. Scott looking black enough, muriate of morphia, slept from 9 till 11, awoke worse and worse, ulceration, I fear, going on. Scotus sent for again at dead of night, came, looking grimmer than ever, bled me till I fainted; about 16 ounces. I awoke and saw him brooding over the pulse with a face smiling with perfect delight. This did the business, and all has been easy enough."

There are many things in common in the two accounts. Both show an interest in every detail which leads to an absence of obedience to the ordinary laws of grammar and composition; in both the victim is frankly scared about himself. But there are differences too. Sir Robert records the accident solemnly, and puts the details in his autobiography, whilst John Brown tells his story in cheery phraseology to his brother in a letter. There is no relieving touch of humour in Sibbald's narration, but rather a cold resentment against circumstances; in Brown's there is a buoyancy of spirits which refuses to be cast down, and even sees a little fun in some of the events. It is the more excellent way of meeting an ailment. He indulges in a little speculation as to etiology: "It was a queer affair, not a common inflammatory sore throat, but as if a fever had been interrupted, aggravated, and destroyed by virulent sore throat, and then it bled to death." His explanation is hardly in the most recent phraseology, but contains a thought or two which are modern enough. His convalescence, too, was a joyous time as compared with Sibbald's slow and almost sullen return to normal. Brown had a literary feast: "I have read Southey's *Life of Bunyan*, the *Elixir of the Devil*, the fifth volume of *The Doctor*, etc., besides lots of Shakespeare's poems, and Carlyle's third volume of the *Revolution*. It is glorious; and now I am regaling myself with *Midshipman Easy* . . ." He looks back on the fight with the malady with no resentment; "a rapid, fierce, but clean disease working its will for three or four days, 40 ounces of blood lost, no sleep for four nights running, desperate pain, total starvation, and then . . . health and a clear inside setting to work to make up."

It is easy to believe of this same doctor that at Chatham during the cholera epidemic he had been found asleep from fatigue by the bedside of a poor woman for whom he had ministered to the end. His is the right way to meet and to fight disease, whether in oneself or in another. Brown would have gone with Coué so far as cheery optimism went, but he would have accepted the "muriate of morphia" too, and whatever nowadays corresponds to the 16 ounces—a vaccine perhaps.

Sibbald's accident was in 1690 and Brown's illness in 1838; but in quite recent times one finds what is perhaps the most detailed description of the course of a malady by the medical man suffering from it which is on record. In 1912 Dr. Leonard Portal Mark published *Acromegaly: A Personal Experience*, and in 158 pages told the story of how from the age of 24 till that of 50 (1879-1905) he experienced and in many cases since he was 14 carefully entered in his diary the symptoms of progressing acromegaly, without himself suspecting that he was a victim of that malady. To this case and to many others in which medical men gave more or less accurate accounts of their sufferings Sir Humphry Rolleston has referred in an interesting and entertaining paper entitled "Diseases described by medical men who suffered with them."<sup>1</sup> Mark's medical friends had diagnosed it thirteen years previously, and some of his near relatives had also been in the secret. Here is the account of his self-discovery:

"I was walking across the north-east corner of Cavendish Square one afternoon in November, 1905, when all at once the idea seized hold of my mind that perhaps I might be suffering from acromegaly, and that it might be the cause of my head troubles. It came upon me like a bolt from the blue. As far as I could remember afterwards, no particular train of thought led up to it. For the first time I thought there might be some connexion between my headaches and the enlargement of my hands and feet. When I got home I at once looked up the subject in Bowdler's *Pathology*, and what was a suspicion was at once confirmed."

The whole story is a remarkable illustration of the not uncommon fact that a medical man may recognize his

<sup>1</sup> *The Mustary Surgeon*, June, 1921.

president, in the chair. It was reported that the work of the hospital was now carried on at four treatment centres (Camden Road, Lewisham Park, Holborn, and Clapham Common) and at ten borough council clinics in London, and that during the year there had been 13,437 attendances, including 4,788 cases which were dealt with by extraction. The London County Council had arranged to deal with over 3,000 cases during the present year—a considerable increase over any previous year—at the Lewisham school treatment centre. Valuable work was being done at the council clinics at Battersea and Paddington. Sir Harry Baldwin praised the work of the hospital as one which performed a first-class service for people who were not well-to-do but who did not desire to be treated on an entirely charitable basis. He was glad that such an institution was having to enlarge its borders and was paying its way. The members of the dental staff were required not only to hold the L.D.S. diploma, but to be members of the British Dental Association. He went on to speak of the proper measures to be taken to prevent dental decay; these were really three in number: (1) the proper selection of food, including a sufficiency of such foods as furnished the vitamins or accessory factors; (2) oral hygiene, in which he believed gum friction twice a day to be much more important than repeated tooth brushing; and (3) a little dentistry at the right time.

## Scotland.

### A CONVALESCENT HOSPITAL.

THE first portion of the new Astley-Ainslie Institution for the reception of convalescent patients from the Royal Infirmary of Edinburgh has been opened. This institution, for which there is now available a sum of over £600,000, is the outcome of the beneficence of the late Mr. David Ainslie of Costerton, Midlothian, who died in 1900 and directed that the residue of his large fortune should accumulate for fifteen years for this purpose. The general idea of the scheme is to provide an institution midway between a general hospital and a convalescent home. When fully equipped it will be able to receive between 150 and 200 patients. The type of patient for whom it is intended are those who, though not yet able to walk about, have a good chance of being restored to health; it is not designed for incurable diseases or cases of dangerous illness. It is to be equipped with modern facilities for scientific treatment and research, so that the patients may be followed up by the physicians and surgeons under whose care they have been originally in the Royal Infirmary. Sheriff G. L. Crole, the Chairman of the Governors, in performing the opening ceremony, stated that no other such institution existed in Britain, or even in America. The governors had acquired four contiguous properties—Canaan Park, Canaan House, Millbank, and Southbank, beautifully situated and beautifully wooded in the southern suburbs of Edinburgh. The Board of the Royal Infirmary was represented on the Board of the Institution, but its management and funds were entirely separate. The unit now open for patients is Canaan Park House, which has been remodelled by Mr. John Jerdan, F.R.I.B.A., so that it consists of a two-story building with open-air verandahs having a southern exposure and attractive outlook on the Blackford Hill. This and the other three units to be opened later are old mansion houses surrounded by grounds extending to some twenty-five acres, so that the convalescent patients will have ample scope for exercise and treatment by open air and sunshine.

### THE LATE SIR ISAAC BAYLEY BALFOUR.

A movement has been set on foot to establish a memorial to the late Sir Isaac Bayley Balfour, who for thirty-four years was professor of botany in the University of Edinburgh and Regius keeper of the Botanic Gardens, Edinburgh. He had, with the Forestry Commission and the Office of Works, arranged for the establishment of a forestry station where plants and trees imported and raised in the Edinburgh Botanic Garden could be cultivated under more favourable conditions. An area of fifty acres on the commission's estate in Glenbranter Forest, Argyllshire, between

the Firth of Clyde and Loch Fyne, will be used for this purpose; it will be under the superintendence of the Regius keeper, and will be called the Bayley Balfour arboretum or garden. The expense of maintaining it will be small, as land, house accommodation, plants, and trees are already provided, and it is proposed that the memorial should take the form of a rest house for visitors, who desire to spend some days at the place. Simple accommodation, a caretaker, and botanical books of reference will be provided if sufficient funds are forthcoming. A small executive committee has been formed, and Mr. John Sutherland, 25, Drumsheugh Gardens, Edinburgh, is acting as honorary secretary and treasurer.

### CONFERENCE OF THE NATIONAL COUNCIL OF WOMEN.

The annual meeting and conference of the National Council of Women of Great Britain and Ireland was held in Edinburgh under the presidency of Lady Frances Balfour. This Council, which was founded twenty-seven years ago, is interdenominational and non-political; it seeks to raise the level of citizenship and gives attention to the supervision of bills before Parliament affecting women and children, the promotion of health measures, educational reforms, and improvement of industrial conditions. About 600 representatives from all parts of the country attended the conference, which devoted a considerable amount of the time to questions affecting children. Mrs. George Cadbury, vice-president of the Council, proposed a resolution urging the Government and local education authorities to find funds for the further development of the School Medical Service. The Rev. Dr. J. Harry Miller, warden of New College Settlement, Edinburgh, gave an address on the delinquent child. Statistics showed that the age at which delinquency became most evident was between 14 and 17, and that Sunday was the day on which most offences were committed. Outlet for youthful energy in adolescence should be provided, and there was much need for halls, gymnasia, and other places of wholesome recreation.

### RECTORIAL ELECTION IN EDINBURGH.

The triennial election of a Lord Rector for Edinburgh University took place on October 27th. The candidates were Mr. Stanley Baldwin, Prime Minister (Unionist); Lord Buckmaster (Liberal); and Mr. Bertrand Russell (Labour). Mr. Baldwin was elected, in succession to Mr. Lloyd George, with 1,236 votes as against 488 votes for Lord Buckmaster and 261 for Mr. Bertrand Russell. The rival parties of Unionists and Liberals engaged during the progress of the voting in the time-honoured "battle" for the steps of the quadrangle, and in the evening joined in a torchlight procession through the streets of Edinburgh.

## Ireland.

### ROYAL VICTORIA HOSPITAL, BELFAST.

THE opening address of the session was delivered by Professor A. Fullerton, C.B., C.M.G., in the King Edward VII Memorial Hall of the hospital on October 23rd. Mr. Mitchell, chairman of the staff, presided, and Dr. Lindsay, emeritus professor of medicine, and Mr. Sinclair, emeritus professor of surgery, with a large attendance of the staff of the hospital and students, were present. The chairman, in a few introductory remarks, called on Professor Fullerton, who welcomed the students to another year's work. He hoped they did not come with the object of riches nor of social advancement; the doctor was too often the butt of the novelist and of the playwright. Unwholesome and too flagrant competition amongst themselves in practice, and flat contradiction in the witness-box, lowered the respect of the community for them, and injured the prestige of the profession. Still there must be no barrier to all of good character in entering their ranks. Some were born into the profession, and breathed a doctor's atmosphere from their earliest years; some were guided by a trivial circumstance; but others, the idealists and enthusiasts, whom nothing could turn aside nor make waver in the pursuit of high scientific medicine, the discovery of knowledge, the prevention of disease, the relief of suffering—these entered medicine because simply they must; they had no choice;

lanugo grows freely, and the epidermis develops the epidermis (described by Welcker in 1864) which furnishes the soapy vernix caseosa so conspicuous on the skin of a newborn child. In an embryo the whole of the epidermis consists of a single layer of cells. Later this becomes double and the superficial layer is the epidermis. About the eighth month the epidermis is cast off, mixed with grease from the sebaceous glands, and is cast off, mixed with grease.

sists and forms a collodion-like envelope over the foetus, protecting the foetus, producing the combe appearance which recalls the harlequin which recalls the harlequin (Fig. 5). The epidermis persists in aquatic creatures such as frogs and salamanders; it protects them from maceration. The human foetus is an aquatic animal while developing in the hydrosphere; the epidermis and the vernix caseosa protect it from maceration. Normal pregnancy terminates with the expulsion of the foetus and the by-products of its glandular organs. If all goes well it becomes an air-breathing mammal. In some times happens that a foetus cannot be expelled. In this event the placenta on which its life depends ceases to act and slowly disappears. The amniotic fluid dries up, the foetus dies, shrinks, mummifies, and eventually its tissues become calcified.

# Placenta.

## The life of an intrauterine foetus is dominated by the placenta.

An embryo, the essential element of an ovarian dermoid, may contain nearly every organ required for the equipment of a foetus: skin with its essential glands, hair and teeth, pigment and nerves, limbs with cartilage and bone, fat and muscle, brain and spinal cord, nerves and ganglia, an eye, gut, and Auerbach's plexus (Nicholson).

For many years pathologists limited their search to the histology of these lumps. Professor S. G. Shattock critically reconstructed some of the sections. For him Grey matter enclosed in dura mater is a miniature brain. C. E. Shattock removed an ovarian tumour the size of a basketball from a girl aged 2½ years. The tumour on median section disclosed an embryo as an acornus-embryoma; it is a byzoma which can be interpreted as an acornus-embryoma; it is only of a hydrocephalic head. The vault is membranous and the base cartilaginous. A piece of hairy scalp is attached to the head and, near it, some tissue consisting of groups of ganglia furnished with large typical nerve cells.

The importance of interpreting the gross features of embryos, with the aid of histological details, adds a new interest to these deformed lumps; they seem like misdirected embryologic energy. The ovarian dermoid shown in Fig. 6

Fig. 6.—Segment of a huge mucous ovarian tumour presenting an embryoma, d, bedecked with a tuft of lanugo, a. (Museum, St. Thomas's Hospital.)

Fig. 7.—Loculi of an ovarian tumour lined with big muscle-laden epithelium. (Magnified.)

is actually the size of a coco-nut and contained the usual mixture of grease and hair. A remnant of the ovary is seen at the lower pole of the tumour and immediately adjacent there is a patch of skin covered with reddish hair resembling a piece of scalp. Two teeth, an incisor and a bicuspid, are fully erupted. The tissue immediately under the skin contains a collection of nerve tissue with cells like those in grey matter of the brain. The skin, hair, teeth, and nerve tissue may be interpreted as representing the cephalic end of an ovarian embryoma (Watrick). The loose matter filling the cyst is furnished by sebaceous glands, hair, and desquamating epidermis. The cyst wall, to meet requirements, grows in a most accommodating manner. It is certain that an ovarian embryoma contains active organs, especially skin, which is continually discharging sebum and sweat, and shedding epidermic cells and hair. The embryo has no time limit like a foetus, not being dependent on a placenta, and though it rarely exceeds the dimensions of a rat the products of its activity accumulate in the bag which encompasses it and amount to three litres or more. Occasionally the pressure of the accumulated organic rubbish bursts the sac and escapes into the peritoneal cavity, which may become so distended that the belly wall pits on pressure like dough. Sometimes the epidermal elements which escape from the sac migrate themselves on the peritoneum. In such circumstances hundreds of little islands of skin bearing tufts of lanugo dot the peritoneal surface of the intestines, liver, and omentum.

## METAMORPHIC GLANDULAR TUMORS OF THE OVARY.

These are the biggest tumours which grow in women. Some of the bigger examples have been recorded. The loculi in such tumours vary in size and their walls are lined with soft tissue covered with a single layer of large columnar cells heavily charged with mucin (Fig. 7). The membrane lining the loculi is arranged in depressions, bays, and narrow recesses, recalling in their arrangement the simple glands of the large intestine. The amount of mucus furnished by them is often very great; as there are no excretory ducts for the escape of the secretion it accumulates in the loculi, which become enormously distended by the

the chief factor. So far we have been dealing with ovarian embryomas in which skin played the prominent part in furnishing waste products. We must now consider some parallel conditions in which mucous membrane is metamorphosed into glandular tissue. The amount of mucus furnished by them is often very great; as there are no excretory ducts for the escape of the secretion it accumulates in the loculi, which become enormously distended by the

clinical teaching units equal in value, superior even because of their variety, to the professorial units. All indications are that our own students will be greatly encouraged to send their cases to the Middlesex Hospital, from the knowledge that in addition to their efficient treatment full use will also be made of their value for teaching and research.

The action of the London Hospital to-day, in modifying the professorial unit system, after a full and fair trial, for the reasons and along lines which we advocated some time ago, still further encourages us in our belief that on the progressive development of this registrar system depends the successful solution of the teaching and of the research problems which the growing complexity of modern surgery, as of medicine and obstetrics, has set our schools of medicine.—I am, etc.,

W. SAMPSON HANDLEY,  
Chairman of the Medical Committee  
of the Middlesex Hospital.

October 30th.

P.S.—The appended extract is taken from a letter of March 14th, 1921, to the University Grants Committee, drafted by our Dean, Mr. A. E. Webb-Johnson. It shows the views held by the governing body and staff of the Middlesex Hospital at that time.

"... The governing body and staff of the Middlesex Hospital Medical School quite realize the advantages that may be expected from the adoption of the unit system, but feel that whole-time professors will not carry that system to its best and fullest degree of development. In the unit system under part-time directors they see great opportunities for the improvement of clinical teaching and research, and the general improvement of the practice of medicine, surgery, and obstetrics, both in hospital and private work. Chosen men will be given great opportunities, but in the opinion of the Council and staff these opportunities might be given to the whole staff of the hospital with greater advantage to teaching and research. They believe that this can be achieved with the expenditure of a third of the amount contemplated under the unit system. . . ."

SIR,—To one who has no connexion with any of the clinical units in London, but who has always regarded the inception of the scheme with interest and sympathy, Mr. Souttar's letter in your issue of October 27th (p. 785) has provided a rather unwelcome surprise.

In the first place, everyone is conversant with the excellent work that has been done at the London Hospital, particularly on certain aspects of surgical technique. In the second place, if the London surgical unit has failed in spite of much excellent work, is this an indication that the other surgical units, and perhaps even medical units, will fail also? In view of the importance of the subject it might be as well to examine the position more closely.

The clinical units in London arose from the feeling that not enough research work was being carried out at the London schools, and consequently that London students were missing the university element in their education, which means that they were not being taught by men who were themselves engaged in advancing the knowledge of these subjects. There was little likelihood of research being carried out by physicians and surgeons who had to make their living and keep up a certain state in the most expensive part of London. The advantages of the scheme seemed to lie in the fact that the work of the clinical units was to be carried on side by side with the other work of the hospital, that a student during his career would enjoy both types of education, and that the aim and scope of the education would be rather different in the clinical unit and in the other parallel units of the hospital.

These facts, if true, would seem to dispose of some of the earlier considerations brought forward by Mr. Souttar in his letter. The student "must learn how to deal with human beings who are ill and to discover those from whom he may best obtain assistance when he is out in the world and on his own responsibility." Undoubtedly he must, though I may be forgiven if I refuse to believe that this is more important than the technical knowledge of his profession, as Mr. Souttar seems to imply. Still, if the student is brought into direct contact with the advance of knowledge in the clinical unit, he may well learn the other part of his profession from his other teachers, who are in private practice themselves.

Much the same argument applies to the whole-time teacher himself. It is surely a curious way of describing

his outlook to say that his horizon is narrowed to the wards and laboratories of his hospital, when these constitute the very field of his researches.

But I must confess that a still greater surprise awaited me. Mr. Souttar says that research in the surgical unit failed because the special cases so essential to research and to teaching were no longer being sent to the surgical unit. Does surgical research require special cases? I should have thought that the function of the surgical unit would be to investigate the common everyday cases met with in the surgical wards, of which our ignorance is at present sufficiently profound. For instance, if rheumatoid arthritis had been chosen for study, my experience teaches me that the researcher would have been overwhelmed with cases. He could also have applied to the infirmaries. Similarly, if the biochemical relationships of cancer as it occurs in the human body had been chosen, surely sufficient cases would have been forthcoming.

After all, what is surgical research? Sir Berkeley Moynihan has described himself as a physician compelled to practise surgery, and this suggests that there cannot be so very much difference between research in surgery and research in medicine. Surely in either subject research consists in investigating the causes, relationships, and treatment of the diseases met with in the medical or surgical wards, and nowadays great advances are possible owing to the numerous experimental methods elaborated since the beginning of the century.

A paragraph in Sir George Newman's report suggests to my mind that these possibilities of research have not been fully realized in the surgical unit at the London Hospital. It is there stated that "the very thorough system of examination and note-taking is regarded as chief contribution to research." But this is no more than has been carried out by practising physicians and surgeons for a hundred years. It entails careful clinical observations, the co-ordination of certain laboratory findings, and above all ample secretarial assistance. Any careful surgeon or physician in practice could undertake it. A whole-time clinical unit would surely be unnecessary. But will the great advances of medicine and surgery of the future be made by such means? Most emphatically, No! The experimental method will be necessary.—I am, etc.,

October 29th.

A LONDON TEACHER.

#### CHRONIC INTESTINAL STASIS AND CANCER.

SIR,—Sir Arbuthnot Lane's address on chronic intestinal stasis and cancer reported in the JOURNAL (October 27th, p. 745) and your comments thereon give food for thought, for does he not attribute to its baneful influence nearly all the diseases to which the flesh is heir?

But a certain amount of intestinal stasis is physiological, and the bowel is specially designed to achieve stasis for purposes of absorption. Then why is it that this stasis, which ought to be only physiological, so often becomes pathological? Is it not because the lining membrane of the bowel is damaged by the continual use of irritating aperients?

More than forty years of general practice have convinced me of the evils produced by this pernicious habit, which in civilized communities has become well-nigh universal. The habit is generally contracted in the early years of life, and thereby one of Nature's most important periodical arrangements is interfered with and put out of gear, and the disastrous results show themselves later on.—I am, etc.,

Bournemouth, October 27th.

JOHN C. UNTHOFF.

SIR,—Surely if the teaching of Sir Arbuthnot Lane (BRITISH MEDICAL JOURNAL, October 27th, p. 745) on the widespread effects and causation of intestinal stasis is true, it is the greatest and most illuminating truth that has been uttered in the realm of medical science in all the centuries. What other contribution to the etiology of disease, mental and bodily, is there to compare with it in its comprehensiveness, its simplicity, and its appeal to the common sense of doctors and laity alike? Can it, truth be refuted? Can it be that, in its simplicity and in the enthusiasm of the teacher, lie the reasons that it has not hitherto been accepted with the acclamation it deserves? It seems to me

## HEART DISEASE IN EARLY LIFE.

SIR,—In reading the discussion reported in your issue of October 20th, I am reminded that in rheumatic infection one used to consider the presence of a positive glycogen reaction of the leucocytes concurrent with the activity of a carditis. When the reaction became negative the activity of the carditis was regarded as terminated.

Is this test now discarded? It had the merit of simplicity and helpfulness.—I am, etc.,

Edington, Birmingham, Oct. 23rd. W. J. BURNS SELKIRE.

## THE TREATMENT OF TUBERCULOSIS BY THE SPAHLINGER METHOD.

SIR,—The letter on this subject which you published in your issue of October 20th (p. 734) from Dr. Cheater is likely to produce a false impression. I will therefore try to reply to his points seriatim, in so far as this is possible.

In the first place he asks: "Why has not M. Spahlinger placed his discoveries before the medical and scientific world?" The answer is that M. Spahlinger has already done so. Communications were made to the Académie de Médecine and to the Académie des Sciences in Paris, and the *Lancet* published a note on this method in January, 1922. In these statements the principles on which his work is based were explained.

Dr. Cheater asserts that my statement to the effect that there is no secret about the preparation of the remedies is at variance with the report of the Chief Medical Officer to the Ministry of Health. I repeat that there is no secret about the principles underlying the production of these remedies. It is quite true that the details of the technique remain undisclosed for the time being, but that is to prevent irresponsible persons from producing hurriedly prepared serums and vaccines and so discrediting the remedy.

He then goes on to say, "an offer was unofficially made [by the Ministry] to M. Spahlinger for a medical committee to investigate his method of treatment," and he asks, "Why did not M. Spahlinger accept this offer, especially as he had four hundred cases already treated?" I have carefully studied the report, but I cannot find anything which bears this out. The implication clearly is that M. Spahlinger refused to allow the Ministry to investigate. This is the exact reverse of the truth. So far from declining investigation, M. Spahlinger on several occasions, in 1921 and 1922, asked the Ministry to investigate, with the result that Dr. McNalty was sent to Geneva for this purpose in July, 1922. The outcome of the visit is recorded in the report to which Dr. Cheater refers. The "unofficial offer" referred to by Dr. Cheater was sent in August, 1922, by the Chief Medical Officer to the Ministry of Health, who congratulated M. Spahlinger upon the cases reported on by Dr. McNalty, and suggested that fifty cases should be treated in England by a small expert committee of medical men to demonstrate the efficacy of the treatment. If he had read the report to the end he would have seen that the Chief Medical Officer himself explains why M. Spahlinger was unable to accept this offer. There was no serum.

With regard to the disclosure of the technique, every medical man and bacteriologist who has investigated the work at Geneva (including the representatives of the Ministry of Health) knows the technical difficulties and precision required in the production of these remedies. They will agree with me in opposing any premature publication of the technical details of the manufacture which would enable large quantities of ineffective preparations, said to be made according to Spahlinger's technique, to be hastily placed on the market, thus discrediting the treatment in the eyes of the medical profession.

Dr. Cheater asks why M. Spahlinger refused offers of several hundred thousand pounds. I thought I had made it clear in my last letter that the offers were for commercial interests—that is, for trading monopolies. M. Spahlinger is opposed to any form of monopoly run

for profit and requiring that the formulæ should remain undisclosed.

Dr. Cheater refers to "bacteriologists more favourably situated than" M. Spahlinger. Who may they be? Spahlinger has the specially trained staff to carry on this most precise and delicate work and a laboratory of which no counterpart exists, fitted with unique and original apparatus invented by him to produce his vaccines and serums. Only to reproduce the plant necessary to carry on this work would cost £20,000 to £30,000. The Chief Medical Officer to the Ministry of Health refers in his report to the fact that "M. Spahlinger controls and directs the work of his large, well equipped bacteriological institute and experimental farm, and the staff have all been trained by him in his own special methods."

All who have visited the institute—and the visitors have been numerous and distinguished—have been favourably impressed with the character of M. Spahlinger's work, and with his sincere desire to place his remedies at the disposal of mankind.—I am, etc.,

Manchester, Oct. 23rd.

THOMAS WATTS, M.D., M.P.

SIR,—I am pleased to see the letter of Dr. Nabarro. I had the privilege of accompanying him on the visit to M. Spahlinger's laboratory at Geneva, and can confirm all he says. My interest in the problems of tuberculosis—dating from the day of Koch's publication of his discovery—took me to the intensive course of lectures and demonstrations on heliotherapy at Leysin. This course, commencing at about 8 a.m. daily and ending any time after 8 p.m., was attended by medical men from all over Europe and from South America, Canada, and the United States. I regret to say only three British general practitioners were present. It was at a lecture by Dr. Stephanie of Montana, a pioneer of Swiss sanatorium treatment, that I heard of M. Spahlinger and his work for the first time. However, I know enough of bacteriology and clinical tuberculosis—having served for two years under the late Professor Delépine of the Manchester Public Health Laboratory, who devoted himself specially to tuberculosis—to be able, after the inspection of M. Spahlinger's work, to form the opinion that it would be a crime against humanity to allow that work to lapse. With the characteristics of genius he appears to have thought of everything in the search for a cure. I draw the attention of my colleagues to the unique choice of biological material which was in correspondence with the results of a statistical investigation I made amongst the 1,200 tuberculous patients of Dr. Rollier at Leysin. I have in my pocket the offer of a London financier, failing other assistance, to find the money to commercialize M. Spahlinger's serum. This method of production has hitherto been refused by M. Spahlinger for the same good reasons which also meet Dr. Cheater's objection.—I am, etc.,

Luton, Oct. 23th.

JOHN BIRCH.

SIR,—I was very pleased to read Dr. Leonard Williams's letter in your issue of October 27th (p. 786), as he practically answers my queries why M. Spahlinger had not published his technique. There is just one point in the last paragraph of his letter which I should like to rectify—namely, that a representative of the Ministry of Health was not refused permission by M. Spahlinger to investigate his treatment, but that the latter was unable to accept the proposal for a committee to do so. I refer Dr. Williams to page 95 of the report of the Chief Medical Officer to the Ministry of Health for 1922, where this matter is fully set forth.

I am also in cordial agreement with Dr. Nabarro that tuberculosis is of international importance and that no stone should be left unturned to discover a definite and permanent way of successfully combating this disease. For this reason I am still of the opinion that every new discovery, whether great or small, should be published as soon as possible so that other workers in the same field might perhaps derive assistance from it, and the ultimate object be the sooner achieved.—I am, etc.,

GEORGE W. CHEATER, M.B., D.P.H.

Whipps Cross, E., Oct. 29th.

"Hygiene" in the *Times* edition of the *Encyclopaedia Britannica*, 1902; the chapters on "Air" and "Military Hygiene" in Murphy and Stevenson's *Treatise on Hygiene and Public Health*, 1893; and that on "Hygiene of the Tropics" in Davidson's *Diseases of Warm Climates*, 1893.

He married Fanny, daughter of Surgeon-General J. McIlree, A.M.S., and had one daughter.

**THE LATE SIR WILLIAM EDWARDS.**—"A Brother Officer" writes: Sir William Edwards was eminently human, and therefore a very lovable character. Active in body and simple in his habits, he had absolutely no "frills," but was always the same—kindly, humorous, and withal shrewd. He was never spoilt by good fortune or unduly depressed for long by adversity. As the head of his service or as a private friend he was still—himself. He was an ideal chief. He thoroughly identified himself with the work, aspirations, and interests of his subordinates, and thus created confidence which drew them along with him. Nothing pleased him so much as ensuring that they got their meed and more of credit, when success was at least as much due to his loyal backing, which he modestly kept in the background. I personally owe more than I can say to his support at a critical juncture, and there are doubtless many others similarly indebted to him, though it is known only to themselves. Within a year of his appointment to be Director-General the difficult question of the revision of pay in the I.M.S. came up for settlement. It is only just to his memory to say that he met with a degree of factious opposition, personal discouragement, and even worse, which would have baffled a less single-minded or less honest man. When he was created K.C.I.E. in 1922 the honour was already overdue, but it did not come from India. It is even more difficult to write of him in his private capacity. He was a great reader and had a fund of miscellaneous information which he never obtruded, though it would out at times in the most unexpected way. He was a very entertaining companion, and would on occasion give shrewd criticisms on men and affairs. Though his opinions on others were at times trenchant, they were always just and never unkind. He was both a delightful guest and an admirable host. Modest in his estimation of himself, generous in his appreciation of others, wise in counsel, and unswerving in loyalty to his subordinates, we mourn the loss of a dear friend and—as we say in India—a *real Sahib*.

**THE LATE PROFESSOR W. ASHLEY CUMMINS.**—The funeral of the late Professor W. E. Ashley Cummins of University College, Cork, took place on October 20th, at Little Island churchyard, and was attended by a large and representative assembly, which included nearly all the members of the medical profession in Cork, the leading members of other professions, and many of the students of University College, Cork. At St. Finbarr's Cathedral at the morning service on October 21st, the preacher paid an eloquent tribute to the character of Professor Cummins. The following tribute from the medical profession in Cork appeared in the *Cork Examiner* on October 22nd:

"The Cork medical profession records with deep regret the great deprivation it has suffered by the death of Dr. W. Ashley Cummins, who continually occupied an honoured place in the estimation of each and every member. He had filled with integrity the many important positions to which he had been elected during a period of many years. His trained intelligence was always at the service of the members of his profession, who looked for his advice and co-operation in the several intricate problems connected with the daily life of the practitioner. The Cork medical profession, individually and collectively, sorrow over the loss of a much respected colleague. They feel it will be an impossibility to fill his place now vacant in their councils and deliberations. They beg to tender to Mrs. Cummins and the members of his family their earnest sympathy with them in their very sad bereavement."

By the death of Dr. HARRY GORDON in his 57th year the Natal Division of the British Medical Association has lost a loyal and valued member. Dr. Gordon was the youngest son of the late Rev. J. Gordon, Rector of Norbury, Cheshire, and was a brother of the late Dr. E. Gordon, who was the first medical graduate of the Victoria University. He was educated at the Manchester Grammar School and Owens College and Manchester Royal Infirmary. He took the

diplomas of M.R.C.S. and L.R.C.P. in 1891, and practised for some time in London. On the outbreak of the Boer war he took an appointment as civil surgeon, and went all through the campaign. At the conclusion of the war he joined the Union Castle Line as a surgeon; he remained in that service about ten years, and was well known and highly popular with travellers to and from the colony. On leaving the sea he was for a time resident surgeon at the Addington Hospital, Durban, leaving there to become surgeon to Kynoch's Works and Hospital at Umbogintwini; later he became also medical officer to the Indian Immigration Board. After settling in Umbogintwini he built up a large private practice extending for many miles round. He was one of the best types of general practitioner, and was a very capable surgeon. Two or three years ago his health broke down after an attack of influenza, and in May last came home to England in the hope that the voyage and change would restore him. He stayed some time with an old fellow student and life-long friend—Dr. Thomas Watts, M.P.—at Southport. Unfortunately his health did not improve, and on the return voyage he became so ill that he had to be taken ashore at Cape Town and sent into a nursing home, where he died on October 1st. He leaves a widow and one young son aged 10.

## Universities and Colleges.

### UNIVERSITY OF CAMBRIDGE.

At a congregation held on October 26th the degree of Doctor of Medicine was conferred on F. T. Burkitt and F. R. G. Heaf.

### UNIVERSITY OF ST. ANDREWS.

At a meeting of the University Court of St. Andrews held on October 27th it was reported that Dr. Adam Patrick had accepted the appointment to the chair of medicine and had also been appointed one of the physicians of the Royal Infirmary, Dundee. The Court also approved of the nomination by Professor Patrick of Dr. J. M. Morgan (Dundee) as assistant in the department of medicine.

### ROYAL COLLEGE OF PHYSICIANS OF LONDON.

An ordinary Comitia of the Royal College of Physicians of London was held on Thursday, October 25th, at 5 p.m., the President, Sir Humphry Rolleston, occupying the chair.

The Censors Board reported that Mr. George Denison Stillwell had been appointed Jenks Scholar.

The following candidates were admitted members:

Charles Keith Johnstone Hamilton, L.R.C.P., M.C., M.B.Oxf., Donald Hunter, M.D.Lond., L.R.C.P., Duncan Gerard Lory, M.B.Oxf., William Thomas Nelson, M.B.Sydney, Daniel Nicholson, M.D. Manitoba, Ernest Oscar Adolphus Singer, M.B.Edin., Kenneth Harry Tallerman, M.C., M.B.Camb., L.R.C.P.

Licences to practise physic were granted to the following 168 candidates who had conformed to the by-laws and regulations and passed the required examinations:

W. L. Ackerman, J. C. Almsworth-Davis, R. H. Amn, R. S. Anderson, F. G. A. Armon, I. Atkin, W. Balendra, P. E. Bardoloy, R. B. Baranov, J. S. Benzery, E. M. Berghelm, D. M. Berry, E. J. Blackaby, Margery G. Blackie, L. G. Blair, W. L. Blackmore, D. R. Blunn, A. J. Boase, Hilda A. Bond, E. G. Bradbur, R. T. Brain, A. Broido, C. O. S. H. Brooke, G. G. Brown, J. W. Brown, Mary Buck, B. H. Burns, Lily C. Butler, Kathleen F. Butterfield, F. B. Byrom, C. M. Carruthers, H. K. Christie, D. H. Cockell, M. Cohen, R. A. Col's, A. B. Cooper, H. Cove-Smith, I. S. Cristie, G. J. V. Crosby, D. T. Davies, I. G. Davies, T. D. Dighton, Margaret B. M. Dewhurst, D. Diamond, V. W. Dix, A. F. Doyle, Doris L. Durie, Hilda R. Dutton, N. L. B. V. Eckhoff, L. C. J. Edwards, P. Elman, G. S. W. Evans, W. M. Evans, J. L. Farquharson, S. Farquharson, R. B. Faykes, H. G. Goldwater, T. S. Goodwin, F. M. Goro, L. J. Green, J. V. Griffiths, P. D. Griffiths, C. J. P. Grosvenor, C. C. Halliwell, A. Harbour, H. E. Harri, Doris I. Harston, G. T. Henderson, K. W. Hoilage, G. Hochschild, Frances A. Hogben, E. Holmes, J. W. Hope-Simpson, Madge W. Hubble, D. F. Hutchinson, L. I. Hyder, C. Izatt, C. Ives, E. C. James, A. H. Johns, C. E. Keast, Karin L. E. Kellgren, G. H. Kirkland, C. de W. Kiteat, R. A. E. Klaber, E. H. Koerner, P. L. M. Lanier, Miriam A. Lawson, J. J. Lewins, R. H. Little, A. A. Lucas, A. R. Macdonald, G. B. Medlicham, Margaret D. Mason, G. B. Matthews, G. A. Metcalfe, H. D. N. Miller, G. V. Mitchell, P. McNeill, Moffatt, C. I. N. Morgan, O. G. Morris, N. Moulson, Jeannette F. L. Murray, F. W. G. Nash, F. N. Newell-Kobert, M. F. Nicholls, J. H. Nicholson-Lalley, Muriel L. M. N. rheoto, P. H. O'Donovan, R. J. Oliver, Mary E. Orm-by, Jean Orr-Ewing, E. C. Pulvertaft, P. G. D. J. Parrish, T. W. Preston, C. A. Probert, R. J. V. Reeves, R. D. Reid, W. L. Quintel, K. Rai, W. A. Rankin, J. O. M. Robertson, Sybil H. G. Roberts, H. A. Robertson, Nina L. D. Robertson, Z. Salama, Robinson, T. Robson, D. J. Rose, Marjorie Rushbrooke, Z. Salama, F. H. Scason, J. M. Scott, H. M. Shelley, A. B. Sherwell, Mary M. Sillito, Lucy C. Simpson, A. J. D. Smith, N. B. Smith, L. V. Snowman, A. C. Somerville, M. Sticher, R. M. L. Still, P. O. T. Strange, E. R. S. Sweeney, Annie Sydenham, P. C. M. Taylor, H. Taylor, R. C. Taylor, L. M. Teuten, B. C. Valentine, S. Vaher, H. F. Turney, Helen R. Turver, E. C. G. West, H. Whillie, I. W. D. Vaughan, Kathleen C. Veat, H. G. B. West, H. Whillie, I. W. D. White, A. G. E. Wilcock, Doris Williams, E. L. Williams, E. L. Williams, Esther Wingate, J. Wolstencroft, T. Woodridd, H. Yates.

\* Under the Medical Act, 1875.

THE annual dinner of the Chelsea Clinical Society was held at the Café Royal on October 30th, with the President, Dr. G. Crewdson Thomas, in the chair. The toast of "Prosperity to the Society" was proposed by Dr. J. A. Torrens, Dean of St. George's Hospital Medical School, who praised the valuable work undertaken by such societies, which concentrate on the practical problems of private practice. The President in his reply expressed the gratitude of the society to St. George's Hospital for providing a meeting place. The society was now twenty-seven years old, and had come to the "dangerous age" when original members were passing away. In order to maintain the interest of its members the present session would be devoted to discussions on common diseases as seen in general practice, and he appealed to general practitioners to contribute their experiences. The toast of "The Visitors" was proposed by Sir Sydney Russell-Wells, M.P., who spoke of the services performed in promoting good fellowship within the medical world of London by the Chelsea Clinical, the Hunterian, the Harveian, and the West London Medico-Chirurgical Societies, each of which was represented that evening by its president. The work of these societies did much in modern times to reproduce that spirit of fellowship within the learned world which was a feature of the mediaeval universities of Europe. The toast was responded to by Sir Bruce Bruce-Porter (President of the Hunterian Society) and Sir William Willcox (President of the West London Medico-Chirurgical Society), and the proceedings closed with the health of the Chairman, proposed by Dr. Gordon Lane.

THE fourth congress of the Surgical Society of Central Germany will be held at Brunswick on November 11th, when the following subjects will be discussed: (1) Surgical treatment of epilepsy, introduced by Professor Felix Franke; (2) surgical treatment of hydrocephalus, introduced by Professor Wrede.

THE first meeting of the Petrograd Pathological Society since the war was recently held, and was attended by Professors Lubarsch and Aschoff at the special invitation of the Russian Soviet Government.

THE Montreal Maternity Hospital has been merged with the Royal Victoria Hospital, Montreal, and it is proposed to erect in the grounds of the latter institution a maternity pavilion, thus increasing the teaching facilities of McGill University.

At a joint conference between the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Disease, held at 1, Wimpole Street, on October 30th, the following resolutions were adopted: (1) "That the ultimate fusion of the two societies is desirable." (2) "Subject to the approval of their respective executives this Conference resolves itself into a deputation to the Ministry of Health to urge that 'the law should be altered so as to permit properly qualified chemists to sell *ad hoc* disinfectants, provided such disinfectants are sold in a form approved and with instructions for use approved by some competent authority.'" (3) "That this Conference recommends that the respective executives of the two societies should each appoint not more than five members to form a liaison committee between the two societies and to explore the possibility of fusion."

## Letters, Notes, and Answers.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology Westrand, London*; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westrand, London*; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, *Mediscera Westrand, London*; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Ducillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

"D. G."—We believe that no new edition of Allbutt's *System* will see the light in the next year or two.

#### INFANTILE JAUNDICE.

DR. H. E. BAMBER writes: Is there any association between the time after birth at which the cord of the newborn infant is tied and the tendency to jaundice of the infant? The opinion of a very experienced general practitioner under whom I once worked and who first called my attention to it was that jaundice in the newborn infant was more liable to occur if the cord was tied very soon after birth.

### INCOME TAX.

#### Book Debts.

"J. S. H." asks: Can the inspector of taxes demand a return of the total of outstanding book debts at the end of the financial year, and can he claim tax on a proportion of these debts?

"\* Strictly, the gross amount of the income of the practice is the total value of the debts which the year's work represents—that is, as near as can possibly be ascertained, the actual cash receipts during the year *plus* any increase or less any decrease in the value of the debts outstanding at the end of the year as compared with that at the beginning. The difficulty of estimating correctly or even approximately the value of a medical man's book debts need be no emphasis, and the practice of regarding the theoretical gross income of any year as coinciding with the actual cash receipts in that year is of long standing and general application. It is, of course, based on the obvious truth that where the volume of debts remains fairly constant the two methods of reckoning must produce very nearly the same result in the long run. But where the circumstances of the practice are peculiar so that the inclusion of payment for debts incurred in past years does not approximately balance the exclusion of unpaid debts of the present year, the Revenue authorities are within their rights, both in law and equity, in discarding the cash basis system, and so is the practitioner if he wishes to do so. Unless, however, there are such circumstances in "J. S. H.'s" case—such as the recent taking over of the whole or part of a practice—he would do well to explain the position and oppose a departure from the normal method in his own case.

#### Motor Car Transactions.

"M. D. S." bought a car in 1918 for £273 and sold it in 1922 for £180, buying a car of similar make and power for £390. What allowance can he claim?

"\* The allowance should be £390—£180=£210. The inspector objects on the ground that the more modern car is bound to be an improved model, and that therefore there is a capital improvement. We do not agree with the conclusion he draws. The official witness before the Royal Commission on the Income Tax agreed that where the cost of a machine rose the replacement cost should be determined by the new level of cost. Admitting, for the sake of argument, that the newer model is better in some respects than the old, it nevertheless remains the fact that a precisely similar car would cost as much as—in fact, in all probability, more than—the actual car which was purchased.

### LETTERS, NOTES, ETC.

#### FOREIGN BODY IN THE INTESTINE.

DR. J. F. D. WILLOUGHBY (Southwell, Notts) writes: On October 22nd I was called in to see a child 2 years old who was said to have swallowed a metal pin with a large knob at one end used to fasten the apron to the side of her perambulator. Immediately after she had swallowed it the child was sick, but in thirty-six hours the foreign body had passed through the gullet, stomach, small and large intestines, without the slightest pain or inconvenience. When the pin was passed per anum it had a thick coating of faeces, the result of the soft bulky food she was ordered to take. The large size of the pin and complete absence of symptoms during its passage appeared to me to be of sufficient interest to record. The pin is 12 inches long and the head at its broadest part 1/2 inch wide.

#### CURAÇOA.

VARIOUS versions of Luttrell's punning verses on the illness of the Prince Regent, afterwards George IV, have been given. The following, which was printed by Sir Algernon West in his book of reminiscences, *One City and Many Men*, is probably as correct as any:

Sad news! The Prince is taken ill—  
All will depend on Halford's skill.  
"Tell, Sir Ben," says the physician:  
"How comes he in this low condition?"  
When Bloomfield ventured to announce  
A small excess of cherry bounce,  
The Regent, hearing what was said,  
Raised from the couch his aching head  
And cried in accents weak and low,  
Curaçoa—curaçoa—cure us O Doctor, cure us O.

Sir Ben was the Prince's personal attendant, afterwards Lord Bloomfield.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 41, 43, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.  
A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 215.

ered, but that European patients contracting the disease cally should be repatriated as soon as possible. These marks apply to the pulmonary form of the disease. For uses of surgical tuberculosis the large amount of sunshine and the freshness of the air appear to be distinctly favourable.

### 320. The Treatment of Tetany.

V. RAAB (*Klinische Wochenschrift*, September 3rd, 1923, 1966) refers to the recent work on the acidosis treatment of tetany, and records a case which shows the practical value of treatment of the affection with mono-ammonium phosphate ( $\text{NH}_4\text{H}_2\text{PO}_4$ ), whatever the exact action of the drug may be. The case was one of persisting severe tetany in a girl, which followed an operation for goitre. Parathyroidin tablets were tried, but only temporary benefit allowed. After the attacks had become as many as thirteen in the day, mono-ammonium phosphate was given (2 grams daily, by mouth). The attacks promptly ceased and have not recurred, the electric changes and Chvostek's and Trousseau's symptoms have disappeared, and the general condition has become quite satisfactory.

## Surgery.

### 321. Gastric Symptoms in Chronic Appendicitis.

LÓPEZ-BAENA (*Arch. de med., cir. y esp.*, August 25th, 1923, 373), who records a case in a woman, aged 25, illustrating the truth of Moynihan's dictum that "the most frequent site of gastric ulcer is the right iliac fossa," states that the gastric manifestations of chronic appendicitis may be divided into two groups. (1) The mild or dyspeptic form, which is most frequent in children and is characterized by the following symptoms: loss of appetite, intolerance for certain articles of diet, such as eggs and meat, sensation of fullness, vomiting and fatigue, and a severe pain in the right side, especially on lying. Comby, Broca, and other French writers maintain that chronic appendicitis frequently assumes the form of cyclic vomiting with acetonæmia. In the adult a similar clinical picture is sometimes, though rarely, seen. (2) The gastralgic form. The patients complain of pain of variable degree, which is very like gastric ulcer. In some it occurs directly after food, and in others later. It may be relieved, or on the other hand aggravated, by a meal. Sometimes it radiates towards the appendix. The patients also suffer from aerophagia, nausea, and vomiting. Analysis of the gastric juice shows the presence of hyperchlorhydria and hypersecretion in many cases. Fenwick in 22 out of 112 cases with gastric hypersecretion on which he operated found appendicitis as the only lesion. Some cases, however, show hypochlorhydria and a normal acidity (Hernando). Several explanations have been given of the gastric symptoms of appendicitis. Some regard them as reflex manifestations, a stimulus arising in the appendix causing a spasm of the pylorus which is followed by pain, vomiting, and other gastric symptoms. Others attribute the gastric symptoms to intestinal stasis and the consequent absorption of toxic substances.

### 322. Exposure of the Kidney through the Lumbo-sacral Fascia.

CHER (*Journ. d'Urologie*, July, 1923, p. 7) suggests a route through the lumbo-sacral fascia for the exposure of a kidney of normal size, as one which would cause the minimum of damage with the minimum of manipulation. A vertical skin incision is made over the erector spinae muscle, 3 to 3½ finger-breadths from the line of the spinous processes between the twelfth rib and the posterior superior iliac spine. The posterior lamella of the lumbar aponeurosis is then divided along the same line and the outer border of the erector spinae displaced inwards. The middle lamella of the lumbar aponeurosis is next exposed and divided vertically, just inside the tips of the transverse processes of the lumbar vertebrae, and the quadratus lumborum muscle, now exposed, is split in the direction of its fibres. The ilio-guinal nerve is seen and retracted upwards, the perirenal vessels are divided and, by blunt dissection, the renal pedicle will be found on the right side at the level of the second lumbar transverse process, and on the left side a little lower, at a depth of from 6 to 7 cm. from the surface. The author considers that this route should be of advantage in the following cases: removal of a small atrophic kidney, tied to the ribs and impossible to exteriorize; nephrotomy and nephropexy; for pyelotomy and in certain cases of hydronephrosis; for plastic operations on the pelvis and upper ureter. In those nephrectomies in which great difficulty is anticipated it would be of value for primary ligation of the renal pedicle, after which the kidney may be removed through an oblique lumbar incision. Finally, it may be used for operations on the nerves of the kidney, and for high uretero-lithotomy and other operations on the upper ureter.

### 323. Thoracoplasty for Pulmonary Tuberculosis.

P. BULL (*Norsk. Mag. f. Laegevidenskaben*, June, 1923, p. 521) gives an account of 75 cases of pulmonary tuberculosis operated on by himself, and of 88 cases operated on by other Norwegian surgeons, the operation being extrapleural thoracoplasty. The operation mortality for these 163 cases was 10 per cent. (16 deaths). The following data refer only to the author's 75 cases. In 73 cases tubercle bacilli were demonstrable in the sputum before the operation, yet even before the patients were discharged from hospital after the operation there were as many as 37 whose sputum was negative. This early disappearance of tubercle bacilli from the sputum proved a sign of great prognostic importance, and of 27 patients whose sputum was still positive on discharge from hospital only 2 achieved permanent recovery. On the other hand, of 22 patients whose sputum was negative on discharge or immediately afterwards, 15 were symptom-free from two months to eight years after the operation. A study of the 25 patients who were well and fit for work from one to eight years after the operation showed that as many as 13 had negative sputum on discharge from hospital. In the remaining 7 cases tubercle bacilli ultimately disappeared from the sputum, but in 3 of these cases they took from six to eighteen months to do so. The author, who has been performing thoracoplasties since May 1st, 1914, has made a special study of his first 37 patients, whose operations dated back from three to eight years. Sixteen were still alive, and of them 12 were symptom-free and more or less fit for work. The calculation may therefore be made that a permanent cure can be effected by thoracoplasty in about 32 per cent. of all cases of advanced pulmonary tuberculosis of a more or less unilateral character.

### 324. Prostatism due to Vesical Diverticula.

TANT (*Le Scalpel*, July 28th, 1923, p. 841) records a remarkable case of a man, aged 48, who had all the symptoms of prostatic hypertrophy, including 1 litre of residual urine, but without prostatic enlargement. Treatment gave only transient relief. Chronic cystitis was followed by severe hæmaturia. After six years' ineffectual treatment a further cystoscopy (rendered difficult by the quantity of mucus in the bladder) showed the orifices of two diverticula, each above and internal to the orifices of the corresponding ureters. Skiagrams taken according to the method of Papin (modified by Gayet and Gauthier), after distension of the bladder with a 10 per cent. sodium iodide solution, showed the shadows of large diverticula behind that of the bladder. The patient then emptied his bladder as completely as possible; the act closed the diverticular orifices, and the cavities remained distended with the solution. A second skiagram showed these diverticula. They were subsequently dissected out with difficulty, under spinal anaesthesia. The patient ultimately made a complete recovery. Tant refers to the so-called "prostatism without prostate" described by Guyon, and while not denying the possibility of retention being due to rigidity of the neck of the bladder, he deprecates a too hasty diagnosis of this condition, and states that if we could know all the resections of the vesical neck which have been unsuccessful we might say that this diagnosis often masks our ignorance of the true origin of the retention.

### 325. The Mortality in Surgery of the Thyroid Gland.

C. M. MAYO and J. DE J. PEMBERTON (*Annals of Surgery*, August, 1923, p. 145) remark that to evaluate accurately statistics in the results of operations on patients with goitre the knowledge of two facts is essential—the proportion of goitres with hyperthyroidism, and the basis on which operative mortality is reckoned. In cases without hyperthyroidism the dangers are confined to operative and post-operative accidents, which include hæmorrhage, pulmonary infections, embolism, and infections. When hyperthyroidism is present the greatest danger lies in the disease itself. The reduction of mortality to 1 per cent. in the surgery of exophthalmic goitre depends on (1) cases coming earlier to operation, before the development of visceral degenerative changes; (2) combined medical and surgical treatment, by means of which post-operative acute hyperthyroidism is reduced to a minimum; (3) recognition of the dangers involved in injury to the recurrent laryngeal nerve—this has led the surgeon to greater care in its avoidance. The pre-operative medical treatment consists of rest, diet, adequate fluidity, digitals, and oral administration of iodine (Fugol's solution). A preliminary surgical procedure, such as incision of hot water or ligation, may be carried out as a tolerance test. As preliminary measures are ineffectual in adenomatous goitre with hyperthyroidism, the mortality is dependent on the number of bad risk cases accepted for operation.

haemorrhage of gravity comparable with that of ruptured ectopic gestation was first recorded by Rokitsanski in 1841; it is a rare condition, and many of the earlier cases rest on evidence which is lacking in precision. Three personal cases are described by Tédénat. The first patient, who had a myomatous mass reaching nearly to the umbilicus, had been observed to become more anaemic after several successive menstruations, which were unaccompanied by any increase of the external bleeding; a haematocoele was noted in the posterior cul-de-sac. Two days after this observation menstruation occurred and was associated with increase in size of the haematocoele; external haemorrhage was slight, but progressive signs of internal bleeding led to laparotomy. After hysterectomy, three litres of blood clot were removed from the pouch of Douglas. The source of the haemorrhage was found in multiple erosions of large venous sinuses which lay on the surface of the myomatous mass. In the second patient a myoma was complicated by pyosalpinx; and in the third subacute torsion of a pediculated myoma was present, and probably accounted for the intra-abdominal bleeding.

### 332. Hidroadenoma of the Vulva.

W. M. J. SCHELLEKENS (*Nederl. Tijdschr. v. Geneesk.*, September 22nd, 1923, p. 1212) states that the first case of hidroadenoma of the vulva—that is, a tumour of the vulvar sweat glands—was described in 1892 by Brauer and by Gebhardt in his *Anatomy of the Sexual Organs*—and in greater detail by Schickelé in 1902. As a rule, it is the size of a pea, only slightly raised above the surface of the skin, and may occur either in single or multiple form. It develops in the corium, the connective tissue of which forms a capsule from which strands of connective tissue divide the adenoma into distinct lobules. The tumour itself consists of ramifying ducts, with two layers of epithelium bounded by a membrana propria. The union of several ducts forms cystic dilatations, which are lined with cubical epithelium. Some writers, such as Ruge and Schiffmann, emphasize the resemblance of hidroadenoma to malignant adenoma of the uterus. Although hidroadenoma is usually a benign growth, malignant degeneration sometimes occurs, and it is therefore important that it should be removed early. Schellekens reports a case in a woman, aged 39, in whom the tumour was situated on the left labium majus, and was successfully removed under local anaesthesia.

### 333. Hysterectomy in Pulmonary Tuberculosis.

J. F. BALDWIN (*Surg., Gyn., and Obstet.*, August, 1923, p. 201) recommends that hysterectomy should be performed in certain cases of pulmonary tuberculosis, particularly as an alternative to therapeutic abortion. The author accepts the opinion of certain authorities that in pregnant women with active tuberculosis the induction of abortion is indicated, and he suggests that hysterectomy, by removing the uterus, relieves the necessity for involution and thus saves the strength of the patient. He states that in cases where there are no complications and the patient is of spare build a hysterectomy can be performed in fifteen minutes from the first incision to the adjustment of the last stitch in closing the wound. The entire uterus is removed, and no cervix is left which might cause trouble in the future; the round ligaments and the broad ligaments are brought in so as to support the vagina and the floor of the pelvis is completely covered with peritoneum. The author has performed this operation on many cases under ether anaesthesia and has never seen any indication of trouble arising from the use of ether. He concludes that in selected cases of pulmonary tuberculosis with pregnancy as a complication, and also in menorrhagia, particularly in the presence of traumatism from child-bearing, or uterine hyperplasia, a panhysterectomy will give the patient the best possible opportunity of recovering from the primary disease.

## Pathology.

### 334. Intestinal Peristalsis.

V. E. HENDERSON (*Canadian Med. Assoc. Journ.*, August, 1923, p. 56) reviews recent pharmacological studies in intestinal peristalsis, especially of the small intestine. Pilocarpine and physostigmine increase bowel tonus and movements by stimulating the vagus endings, while pituitary extract produces the same effect through its action on the muscle cells. Atropine, by its action on the vagus endings, relieves spasm without abolishing normal movements or central control, and is valuable in intestinal spasm. When once the bowel tonus has fallen and distension has existed for any length of time neither drugs nor nerve stimulation avail, and consequently it is essential that pharmacological help should be called

upon directly the earliest symptoms of intestinal stasis can be detected, or where there may be any fear of distension developing, and for this purpose physostigmine in 1/64 grain doses every three hours is the best drug. Another point of practical value is demonstrated by the fact that if an isolated piece of bowel tied at both ends is suspended in oxygenated saline, choline, which is produced by all parts of the bowel by the digestion of such foods as lecithin, becomes diffused into the water and has the power of increasing tonus and rhythmic movements, and it has been suggested that in choline we have a hormone which maintains bowel activity. Intravenous injections of 10 mg. of choline hydrochloride per kilogram of body weight were found to restore normal movements in animals in which, from handling or prolonged anaesthesia, the movements had become sluggish. It was further found that, while peristalsis was shallow and failed to move the contained fluid when intestinal tonus was low and the bowel contained sufficient fluid to fill it, respiratory movements were effective, the fluid gradually passing upwards into the stomach to be vomited. Such a process probably more correctly explains faecal vomiting in intestinal stasis than does the usual theory of reversed peristalsis.

### 335. The Digestion of Cellulose in the Human Intestine.

MADAME Y. KHOUVINE (*Ann. de l'Institut Pasteur*, August, 1923, p. 711) reports experimental work in connexion with the digestion of cellulose and the conclusions to be drawn therefrom. She finds that cellulose is split up in the human intestine equally as in that of animals, vegetables such as carrots and cauliflowers disappearing almost completely. The process is attributed to micro-organisms which previously it had not been possible to identify, but in the course of the investigations recorded a bacillus, which she designates the *Bacillus cellulosae dissolvens*, was found to be present in 60 per cent. of cases. The species is difficult to cultivate, only growing in a putrefactive medium such as is constituted by an extract of faecal matter. It is extremely resistant to heat. The spore is only killed after forty-five to fifty minutes' boiling, and resists a 16 per cent. solution of chloroform for six days. The products of disintegration of cellulose were found to include carbonic acid gas, hydrogen, ethyl alcohol, acetic and butyric acids, and a yellow pigment, traces of lactic acid, and substances produced by hydrolysis and precipitated by alcohol. These represent about 60 per cent. of the total cellulose, and the author considers that there should exist saccharides soluble in alcohol which it is proposed to demonstrate in future research. She claims an important place for the *Bacillus cellulosae dissolvens* in the digestion of cellulose, pointing out that, whilst in a pure state it splits up, in sixteen days, 1 gram of cellulose, five times that amount can be dealt with in the presence of other organisms—a condition that exists to a most favourable degree in the intestinal lumen.

### 336. The Connexion of the Cerebro-spinal Fluid with Cerebral Lesions in Epilepsy.

W. E. DANDY (*Johns Hopkins Hosp. Bull.*, August, 1923, p. 245) reminds us that it is the generally accepted belief that the chief function of cerebro-spinal fluid is to protect the brain and spinal cord from the ordinary and extraordinary shocks to which these important structures are subjected. The crania-vertebral chamber in the adult is a fixed cavity, and there can be no expansion or contraction of its walls. Intracranial lesions may be looked upon as space-occupying and destructive—in the first group tumours, abscesses, and the like; in the second group the late results of emboli and thrombi. In tumour growth space is obtained by anaemia directly over the tumour and throughout the brain, also by the destruction of brain tissue. Probably a greater amount of room for the direct expansion of the tumour is obtained through the cerebro-spinal spaces. As a result of inconsistent findings in many cases of epilepsy it is believed that apart from a few cases with the Jacksonian "march" epilepsy is an idiopathic disease. From a series of 75 brains of epileptics exposed at operation the author presents evidence of the frequent presence of gross organic lesions in epilepsy. In most instances he has been able to demonstrate the presence of a cerebral lesion or changes which indicate that a lesion is present. The changes found are (1) dilatation of the ventricles, (2) abnormally shaped ventricles, (3) dilatation of the subarachnoid spaces, (4) softening of the brain, (5) areas of increased density, (6) changes in the meninges. It is believed that these are evidences of actual cerebral lesions, and the frequency of the findings leads to the conclusion that there is a pathological basis for so-called idiopathic epilepsy in a large proportion of cases. Confirmation is obtained by ventriculography, which in a certain proportion of cases shows acquired or congenital distortion of the ventricles.

such delicate structures sometimes acquire malignant power and penetrate blood vessels. Fragments detached from such villi become emboli, and lodge in distant organs, embed themselves, and establish new tumour colonies. This disease of the villi, now well recognized, is described as chorionic cancer.

#### Arachnoid Villi.

It is well known that the pits in the cranial vault, familiar to students of human osteology as the foramina for the Pacchionian bodies, are due to the erosive action of arachnoid tufts; but it is a recent discovery that these villous bodies sometimes grow luxuriantly, overrun the adjacent bones, and produce in them extraordinary changes.

In 1885 Sir William Stokes described the skull of a male Cingalese (Fig. 1), and on the vault of this skull there is a mass of bone resembling a crown of loosely compacted coral. The tissue of this crown is intimately incorporated with the vault of the skull, and the whole mass is permeated with neat vertical pits. Each "pit" is really a tunnel, and as neat as a Pacchionian pit. These tunnels are exaggerated Pacchionian pits produced by pathological arachnoid tufts. Professor S. G. Shattock has made a thin transparent section of the crown, and the tunnels can be seen traversing it completely. There are hundreds of tunnels in this crown, and they recall holes in ship-timber bored by the teredo or those in limestone made by whelks (Pholas).

In recent and unmacrated hyperostoses of this kind arachnoid villi can be demonstrated in the tunnels. In the head of the patient there was a layer of gelatinous material over the bone, between it and the scalp; it also filled the tunnels. The dura adhered to the bone and to the surface of the brain.

When this extraordinary specimen was described by Stokes no one had the least suspicion that such a change could be produced by arachnoid villi. Dr. W. G. Penfield, in 1921, began a careful study of the intracranial tumours preserved in the museum of the National Hospital for the Paralysed and Epileptic, Queen Square, London. He has proved that the soft tissue of the tumour arises within the cranium, pierces the dura, and involves the overlying bone. The action of the tumour elements leads to complete rearrangement of the osseous tissue between the tumour and the scalp. It is a singular clinical feature, in many of the

patients, that the presence of the hard sessile boss of bone was the first sign of disturbance. In some the first symptom is intense pain beneath the bony boss. In such patients epileptic seizures are common. In a few instances the tumour has been attributed to an intensive local injury, such as a blow upon the head.

In addition to the skull of the Cingalese the museum of the Royal College of Surgeons contains a similar and equally remarkable example obtained from a miner, who died in the General Infirmary, Leeds, 1904. Eleven years previously he fell backwards and bruised his head. The bruise did not subside and continued to increase. The man complained of headache and occasional diplopia. With the hope of arresting the growth of the tumour the left external carotid artery was tied, but death followed the operation in ten days. The hyperostosis involves the left parietal, adjacent parts of the occipital, and the squamous portion of the temporal. For the most part the normal tissue has been replaced by exceedingly dense bone, and a plaque-like por-

FIG. 1.—Skull of a male Cingalese, aged 20. The vault of the skull resembles a crown of loosely compacted coral. The mass is traversed by hundreds of tunnels—exaggerated Pacchionian pits—which open on the surface. The orifices are represented, for the sake of emphasis, too big. (Museum, Royal College of Surgeons.)

tion extends within the skull. part of the tumour (Fig. 2).

Skulls changed in this way

could not escape the observations of pathologists. Some examples have been described by French writers as hemicraniosis. The frontal is the bone of preference, but the parietal and squamosal are often involved. The relationship of cranial hyperostosis to meningeal tumours has also been considered by American surgeons—Spiller and Cushing among others.

The relationship of an arachnoid tumour to the osseous elements is well shown in a specimen preserved in the museum of St. Bartholomew's Hospital (Fig. 3). The patient was under the care of Sir James Paget. A section prepared for the microscope, contained in the museum cabinet, shows well the villous nature of the tumour.

The merit of Penfield's excellent essay is his demonstration of the soft tissues which fill the tunnels in the cranial hyperostosis, and I enjoyed the privilege of examining the specimens

FIG. 2.—Portion of the base of a skull to the left of the middle line showing, in section, an immense hyperostosis. F, frontal; P, parietal; O, occipital; F.M., foramen magnum. (Museum, Royal College of Surgeons.)

he prepared for microscopic investigation. Penfield prefers to use the name "endothelioma" for these tumours, but names are only convenient labels, and in this case matter little if we keep in mind the

The skill and care required to remove completely a dog's pancreas successfully is appreciated by surgeons who have performed operations on the pancreas of man. The intimate connexions of the pancreas with the duodenum in dogs is shown in Fig. 4.

#### Colloid Omentum.

Extraordinary examples of functional activity in cancerous epithelium may be studied in the gastro-intestinal canal. The mucous membrane of this tract contains cells that secrete mucus. In the stomach the cell covering is almost entirely formed of them; in a cell swollen with mucus the nucleus is pushed towards the basement membrane. When the mucous membrane is cancerous, the epithelial cells often furnish large quantities of mucus, which infiltrates the omentum and converts it into a gelatinous mass, commonly called "colloid omentum." The mode in which this change is produced can be explained, and my knowledge of it has been obtained

FIG. 5.—Harlequin foetus.

in the course of operations performed on the stomach for the relief of gastric disorders.

When the stomach contains a focus of cancer the cylindrical cells, heavily charged with mucin, permeate its wall, fall into the lesser bag of the peritoneum, engraft themselves, and appear, in the early stages, as small yellow flakes. At this stage microscopic examination shows them to consist of clumps of columnar cells full of mucin. These pathological or secondary foci of cancer act as glands and shed mucus in abundance into the omental fold. Such foci multiply, and being reinforced by cell-showers from the primary focus invade the omentum and convert it into a mass of "colloid" weighing many pounds. Omentum changed in this way sometimes forms such a large mass that it has been mistaken in women for a big ovarian tumour. It is not uncommon when cell-showers of this kind fall from a primary focus in the stomach or the colon for the epithelium to engraft itself on the ovaries and convert them into colloid tumours as big as coco-nuts. Implantation tumours of this kind are by no means rare, and as they are now appreciated by surgeons there is little danger of such enlargements, secondary to primary cancer of the stomach or colon, being mistaken for primary ovarian tumours.

I have considered these conditions especially because, in dealing with the large multilocular glandular tumours of the ovaries, there is a possibility of error unless care is taken in the microscopic examination of the tumour.

#### OVARIAN DERMoids.

Dermoids have an irresistible attraction for me. They prove that many tumours owe their grossness to the accumulation of retained secretions.

The simplest example is a sequestration dermoid on the face or scalp. This takes the form of a globular tumour with a central cavity lined with skin furnished with dermal elements—epidermis, sweat glands, hair bulbs, sebaceous glands. In such tumours the epidermis is continually shed with hair, sweat, and sebaceous grease into the central cavity. The dermoid slowly enlarges in consequence, and a tumour of this kind, no bigger than a pea or a walnut at birth, may in twenty years be as big as a coco-nut. When such a tumour is opened and the contents cleared away the skin lining its cavity will sweat when the patient sweats, and the fluid can be seen oozing from the sweat ducts. The skin lining the tumour is sensitive to the prick of a pin.

The most impressive examples of functioning tumours arise in the ovary, and the growth of our knowledge concerning these tumours reads like a fairy tale. Fifty years ago dermoids puzzled pathologists, but in the interval much knowledge has been gained concerning them. It is now established that these tumours are the products of ova which have become active and developed into ill conditioned foetuses independent of the stimulus of spermatozoa. An ovarian foetus produced in this way is called an embryonal rudiment.

Before dealing with the relation of ovarian embryomas to the products found in their sacs some matters must be considered relating to the activities of a normal uterine foetus.

In the mid-period of gestation the foetus floats freely in a hydrosphere formed by amniotic fluid. There are four sets of organs functional—the placenta on which its life depends, the kidneys, choroid plexuses, and skin with its epitrichium. The urine discharged by the kidneys mingles with the amniotic fluid. If the urine is hindered from

FIG. 6.—Ovarian dermoid. The skin, hair, teeth, and nerve tissue which it contains may be regarded as representing the cephalic end of an ovarian embryoma. From a single woman aged 26. (Museum, Middlesex Hospital.)

escaping the kidneys will become transformed into hydro-nephrotic sacs. The choroid plexuses secrete cerebro-spinal fluid, and if it cannot escape from the fourth ventricle hydrocephalus occurs. This is a common malformation, and museums contain examples by the score. The skin is active,

products of the cells. It is a gelatinous substance now called pseudo-mucin. Often the walls of adjacent loculi rupture and allow neighbouring cavities to communicate, and in this way large chambers form. It is not uncommon for a loculus near the periphery of the tumour to burst and allow the contents to escape into the belly. In some of the cases the amount of pseudo-mucin that collects in the belly is almost beyond belief.

A spinster, aged 54, was under my care in 1899 on account of an enlargement of the belly. The physical signs suggested an accumulation of fluid. The pressure was so great as to produce a hernial protrusion as big as a bantam's egg at the navel, and a similar one over the left femoral ring. A tumour could be felt in the pelvis. I removed three gallons of mucin and a mucigenous tumour of the ovary equal in size to a coco-nut. There was a rent in its capsule opening up three loculi, and through this rent the pseudo-mucin secreted by the mucous membrane lining the loculi escaped into the belly. The tumour was easily removed and the patient reported herself in good health five years after the operation.

Un Chiffonnier.

Many similar cases have been under my care and observation, but all do not end in this simple way. Occasionally, when a mucigenous tumour bursts, clumps of cells escape from the walls and settle on the peritoneum and act as grafts, and become independent tumours, discharging pseudo-mucin, which helps to increase the general mass. In some women hundreds of these pathological glands grow on the serous membrane, and the amount furnished in this way, after the primary tumour has been removed, is so great that it is necessary to open the abdomen annually for the removal of the pseudo-mucin. In removing this material care should be taken to protect the edges of the abdominal incision; it occasionally happens that the epithelial elements in the pseudo-mucin accidentally implanted will grow in the scar and form independent tumours. I have seen them as large as ripe gooseberries.

Surgeons are familiar with these remarkable tumours, concerning which the following facts may be stated: It is not uncommon to find in a woman one ovary occupied with a dermoid and the other converted into a mucigenous cyst. It is not rare to find an ovary transformed into a bilobed tumour one lobe of which is a typical dermoid and the other mucigenous. The inner walls of isolated cavities are often covered with cylindrical epithelium loaded with mucin and indistinguishable from the large cells found on the surface and recesses of the rectal polypi so common in children. Mucigenous tumours are often so large that it is only by chance the embryoma is detected. Quite by chance I saw one on the cut surface of a huge tumour. The embryoma presented as a patch of skin, less than 2 cm. square, bedecked with a tuft of delicate lanugo (Fig. 8).

I have studied the histology of these tumours in season and out of season, and often asked myself the question, Why is the intestinal tract rarely demonstrable in the ovarian embryoma? Gradually I have realized that the mucin (or pseudo-mucin) of these tumours is produced by the gastro-intestinal epithelium of the embryoma, and this, the active agent in the production of mucin, is masked by the accumulated products of its own activity.

The matter may be briefly expressed in this way: In the common kind of ovarian embryoma the cutaneous elements are conspicuous; the products resulting from the activity of the skin preponderate and make up the bulk of the tumour mass. In mucigenous ovarian tumours the so-called "colloid stuff" is furnished by the gastro-intestinal epithelium of the embryoma.

*In dermoid tumours skin prevails.*

*In mucigenous tumours mucous membrane prevails.*

In France the man who picks up rubbish in the streets and collects it in the *hotte* on his back is called a *chiffonnier*. The membranes of a uterine foetus, or the sac of an ovarian embryoma, serve to remind us of the *hotte* of the *chiffonnier*. The simile helps to illustrate the thesis set out in the beginning of this lecture: Many tumours become manifest by the accumulation of the products of their own activity.

## ARSENICAL PIGMENTATION OF THE MOUTH AND SKIN.

BY

RALPH STOCKMAN, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS,  
UNIVERSITY OF GLASGOW.

PIGMENTATION of the skin, varying in depth of colour from a light mottled grey to black-brown, and in extent from a small area to the entire surface of the body, is now well known as one of the occasional effects of the ingestion of arsenic in repeated small doses. It has occurred also very exceptionally and in mild degree after a single large dose.<sup>1</sup> The most detailed account of it has been given by Nielsen,<sup>2</sup> who in the course of his article makes two statements which have also been made by many other writers, either on his authority or their own. He says:

"A deposit of pigment in the mucous membrane of the mouth seems never to have been seen"; and

"A far more trustworthy symptom, which will serve for the diagnosis between arsenical melanosis and argyria and Addison's disease, is the fact pointed out by several writers that in arsenical melanosis the visible mucous membrane is never pigmented. It is true one case has been reported,<sup>3</sup> in which the bullous oculi had been affected by pigmentation, but no case apparently where the mucous membrane of the mouth had been so affected."

I have, however, now met with two cases in which not only was the skin deeply pigmented, but the mucous membrane of the mouth shared markedly in the discoloration. One of these I reported in 1921.<sup>3</sup> It was the case of a woman, aged 49, who had taken liquor arsenicalis daily for six years, and in that time had swallowed about 32,850 minims, equal to 298 grains (19.3 grams), arsenious acid. When I first saw her she had very extensive pigmentation of the skin, and keratosis of the palms and soles. The mucous membrane of the mouth and tongue had a bluish dark tint all over, and on the inner surface of the lower lip there was an irregular deep blue-black patch about the size of a sixpenny piece. She also had cirrhosis of the liver and ascites, but no neuritis.

The second case was that of a man, aged 57, suffering from pernicious anaemia, who developed marked pigmen-
